## ABSTRACT

During a geothermal reconnaissance mission in Burundi in the autumn of 1982, two scientists from the National Energy Authority, Iceland, and one from the Ministry of Public Works, Energy and Mines, Burundi, visited 14 geothermal locations. Fifteen samples of geothermal water, three of cold groundwater and one of gas were collected.

Eight of the locations are outside the western branch of the East African rift valley, but six inside it. All the springs outside it rise through Precambrian rock. The springs at one location inside the rift valley also rise through Precambrian rock, but at the other five through sediments. Using chemical geothermometers the highest probable source temperatures were found at three of these, all situated in the Rusizi valley. It is unlikely that exploitable geothermal reservoirs can be found in the Precambrian rock, but the porosity of the sediments in the Rusizi valley should be adequate for potential exploitation there.

Reservoirs with source temperatures above 100°C probably underlie parts of the Tshibinde volcanic zone south of Lake Kivu. The geothermal manifestations in the Rusizi valley are likely to be a part of this, but other parts of the volcanic zone lie in Zaire and Rwanda. It is recommended that further geological and geophysical studies should cover the whole of this potential geothermal area in co-operation between Burundi, Rwanda and Zaire.

The Geothermal Division of the Icelandic National Energy Authority herewith transmits to the Icelandic International Development Agency its report on a geothermal energy reconnaissance mission to the Republic of Burundi, which was carried out on 30 Aug. - 13 Sept. 1982.

The mission was undertaken in response to a request dated 18 August 1981 from the Minister of Public Works, Energy and Mines in Burundi to the Icelandic Minister of Industry. A proposal was drawn up by the Geothermal Division as to the feasibility and scope of the mission, whereupon a decision was taken to carry out the mission under the auspices of the Icelandic International Development Agency. The cost was borne jointly by the IIDA and the INEA.

Two INEA geothermal scientists, Messrs. Gestur Gíslason geologist and Halldór Ármannsson chemist, undertook the reconnaissance mission, which was carried out with the co-operation of Mr. Liboire Muhagaze, a counterpart from the government of Burundi. Fourteen geothermal sites were visited. Samples of water and gas were drawn and analysed for volatile constituents in Burundi, and samples for complete chemical analysis were sent to the INEA laboratories in Iceland.

The main conclusion emerging from the mission is that only under the Rusizi valley in northwestern Burundi is it likely that an exploitable reservoir with a source temperature of over 100°C will be found. This area is the southeastern part of the Tshibinde volcanic zone, most of which lies in Rwanda and Zaire.

It is recommended that further geological and geophysical studies be carried out in the Rusizi valley in order to better define the boundaries of potential reservoirs. In view of the geographical extension of the Tshibinde volcanic zone within Burundi, Zaire and Rwanda, it would be advantageous if such a study could be carried out in co-operation between these three countries.

Respectfully yours

Guðmundur Pálmason

Director, Geothermal Division, INEA

## 1 INTRODUCTION

In a letter dated 1981.08.18 from the Minister of Public Works Energy and Mines, Burundi, to the Icelandic Minister of Energy and Industry, assistance was requested in estimating the possibilities of utilization of geothermal resources in Burundi. A report by Edeline et al (1981) which included a description of geothermal manifestations in Burundi and analyses of some geothermal waters accompanied the letter.

The Icelandic Ministry requested that Orkustofnun (The National Energy Authority of Iceland) performed the necessary studies. A short preliminary report (Ármansson & Kristmannsdóttir 1981) was handed to the Ministry shortly afterwards. Its recommendation was that further data be obtained so that a fuller assessment could be given. All available data were gathered and a report recommending a reconnaissance mission was published as a result (Gíslason & Ármansson 1982). Furthermore the NEA received a request for technical aid to Burundi in the geothermal field from the Icelandic Foreign Ministry 1982.01.07. The letters to the Icelandic ministries of Industry and Foreign Affairs are printed in Appendix 1.

The recommended reconnaissance mission was undertaken by the authors of this report from 30th August to 13th September 1982.

The results obtained during and after the mission together with the data gathered previous to it form the basis of this report.

In Burundi the research was carried out in cooperation with Mr. Liboire Muhagaze, a counterpart from the government of Burundi which also provided a vehicle, a driver and access to a chemical laboratory.

## 2 EXECUTION OF THE STUDY

### 2.1 Data collection

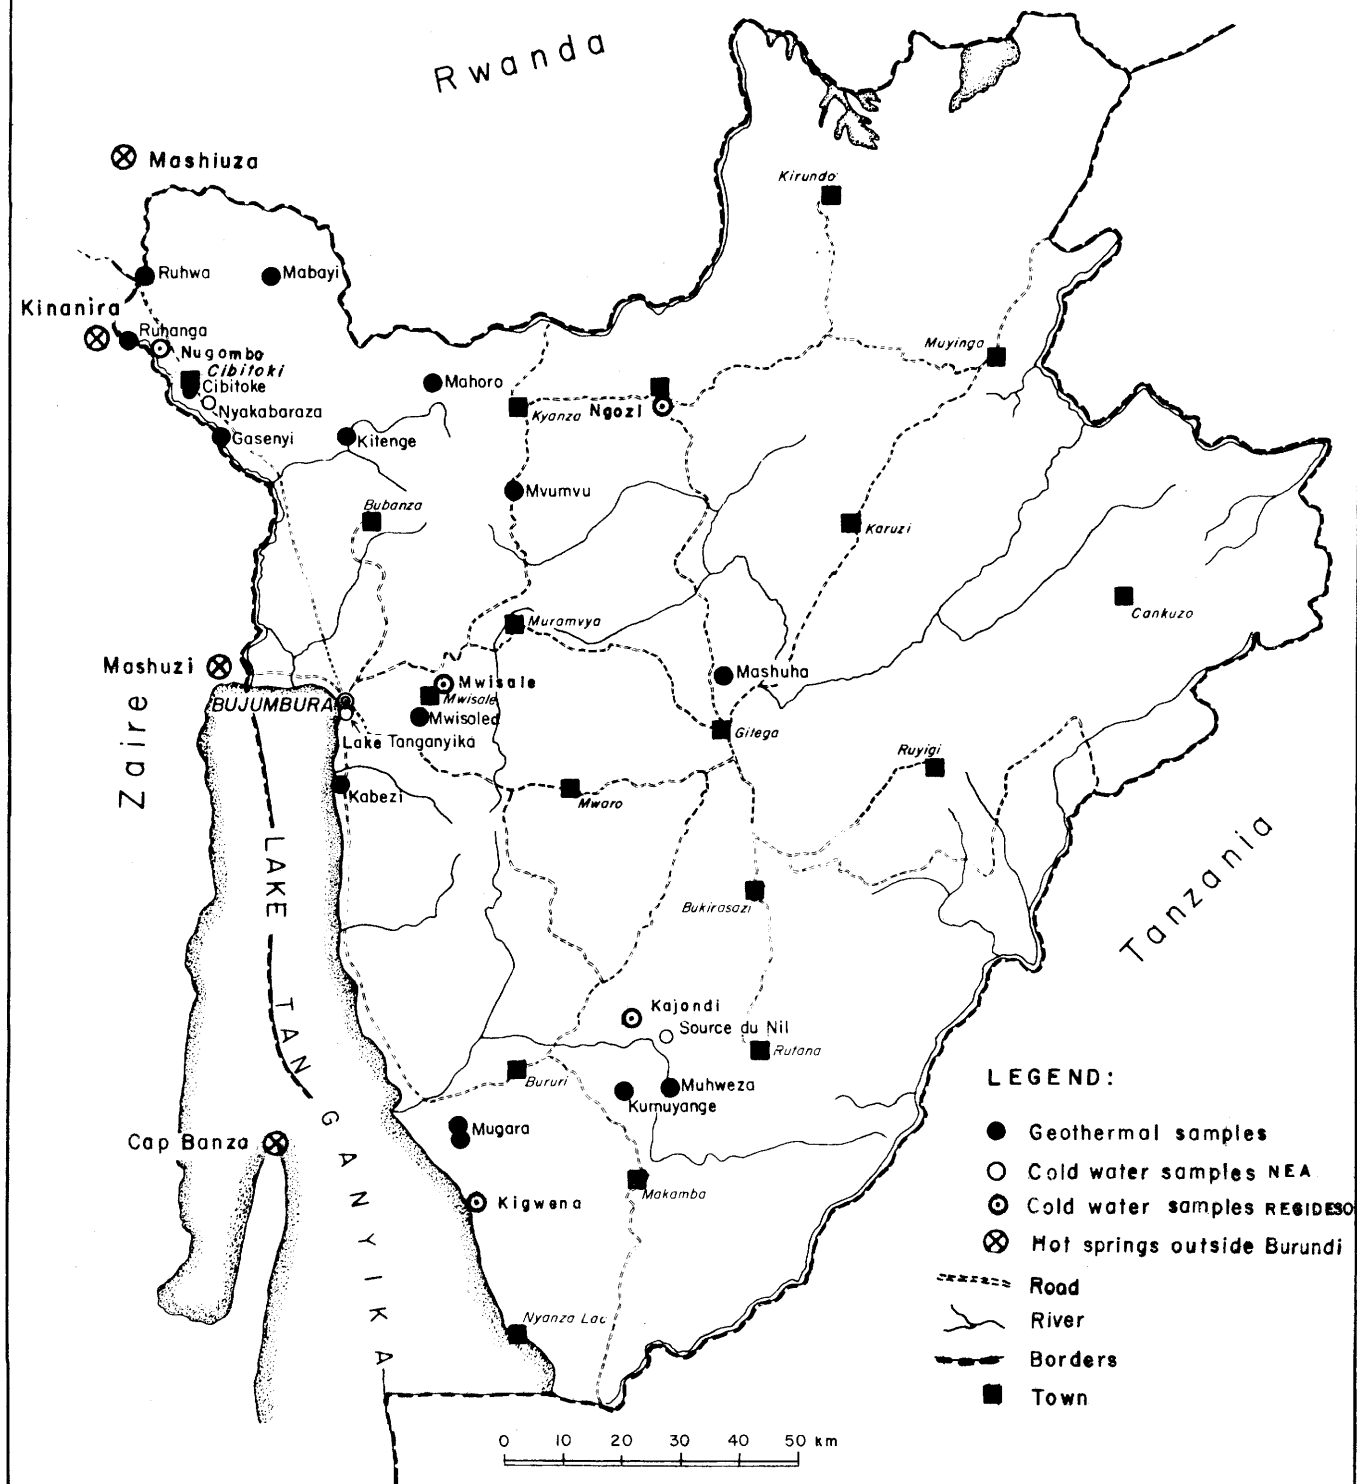

Data on previous geological and geothermal research were obtained from the available literature (McNitt 1969, Deelstra et al 1972, Edeline et al. 1981) and geological and other maps (Ministere des Colonies 1956, Lepersonne & Waleffe 1975, Lepersonne 1977, Waleffe 1979, Waleffe 1981, Radulescu 1981). Data on the chemical composition of cold water in Burundi were supplied by Burundian Water Board, Regideso. Two meetings were held with the directors of geology and general energy and Mr. Muhagaze and one with the Minister of Public Works, Energy and Mines, where information on the country's energy situation and needs were made available. Further details were filled in and inconsistencies corroborated by consulting a report from the World Bank and UNDP (Hughart et al. 1982).

### 2.2 Reconnaissance

The field study was organized in such a way that for most of the time the participants spent their nights in Bujumbura, but their days driving to and stopping at field sites. During the study of the northern part of the country the participants spent one night in a catholic mission house. All known geothermal localities were visited by the authors of this report and Mr L. Muhagaze. The guidance of local people proved very helpful indeed. In fact, the only locality not previously described, i.e. Gasenyi, would not have been found without such local assistance. All localities visited and those for which cold water analyses were obtained are shown in Fig. 1.

Fig. I. Burundi Sampling locations

### 2.3 Methods of surveying, sampling and chemical analysis

At the geothermal sites the main geological features were studied, i.e. rock types, possible faults, the distribution of hot springs and the possibility of mixing between thermal and cold surface water. The flow rate was measured or estimated. The temperature was measured in all springs with a digital thermometer, NEA designed and made, connected to a two-terminal integrated circuit temperature transducer probe on a one metre long bar. At each sampling location three water samples were drawn.

- 1) Raw untreated sample (Ru) into an air-tight 250 ml glass-tube for the analysis of pH, CO<sub>2</sub> and H<sub>2</sub>S.
- 2) Filtered untreated sample (Fu) was filtered through a 0,45 Millipore membrane filter and collected into a one litre plastic bottle for the analysis of SiO<sub>2</sub>, SO<sub>4</sub>, Cl, F and total dissolved solids (TDS).
- 3) Filtered acidified sample (Fa) was filtered as above, acidified with 2 ml 6 N HCl and collected into a one litre plastic bottle for the analysis of Na, K, Ca, Mg and Li.

All the samples were cooled to ca 20°C by passing them through a cooling spiral immersed in ice-water to prevent the formation of gas bubbles in the Ru samples. The analysis for pH, CO<sub>2</sub> and H<sub>2</sub>S was performed daily by the authors at the chemical laboratory of the Department of Geology, Ministry of Public Works, Energy and Mines, Bujumbura. At one location a gas sample was drawn into an air-tight 250 ml glass tube by first filling it with cooled sample water which was subsequently driven out by the gas stream. The analytical methods used in water analysis, their precision and source references are listed in Table 1. The precision of the pH determination is that cited by the producers (Schott-Geräte 1977), that for SiO<sub>2</sub>, Na, K, Ca, Mg, CO<sub>2</sub>, SO<sub>4</sub>, H<sub>2</sub>S and Cl is obtained from the results of the determination of several duplicates of different concentrations in the NEA laboratory, but the one for F and TDS from the results of the multiple determinations of two reference samples of different chemical compositions.

TABLE 1 BURUNDI 1982. Methods of chemical analysis

Constituent	Sample Fraction	Method	Precision	References
pH	Ru	Combined glass electrode Schott type N-62 Meter type CG 718	±0.01 pH	Schott-Geräte 1977
SiO <sub>2</sub>	Fu	Spectrophotometric on yellow ammonium molybdate β-complex after treatment with I <sub>2</sub> and Na <sub>2</sub> S <sub>2</sub> O <sub>3</sub>	1.6%	Strickland 1952 Govett 1961 Elisson 1969
Na	Fa	Atomic absorption spectrometry on solution containing 100 ppm Li	1.4%	Perkin-Elmer 1976 Armannsson & Hauksson 1978
K	Fa	Atomic absorption spectrometry	1.4%	Perkin-Elmer 1976
Li		Atomic absorption spectrometry		Perkin-Elmer 1976
Ca	Fa	Atomic absorption spectrometry on solution containing 2% La	4.3%	Willis 1961 Perkin-Elmer 1976
Mg	Fa	Atomic absorption spectrometry on solution containing 2% La	13.8%	Willis 1961 Perkin-Elmer 1976
CO <sub>2</sub>	Ru	pH adjusted to 8.20 titration with 0.1N HCl to pH 3.80	3.8%	Ellis & Mahon 1977
SO <sub>4</sub> <sup>-2</sup>	Fu	Titration with BaCl <sub>4</sub> using thorin as indicator	2.6%	Henriksen & Bergmann-Paulssen 1974 Gunnlaugsson 1978
H <sub>2</sub> S	Ru	Titration with HgAc <sub>2</sub> using dithizone as indicator	13.7%	Archer 1956 Arnórsson 1969
Cl <sup>-</sup>	Fu	Titration with AgNO <sub>3</sub> using KCrO <sub>4</sub> as indicator (Mohr titration)	2.3%	ASTM 1966
F <sup>-</sup>	Fu	Determination with selective electrodes (ORION 94-09 and 90-01 as reference) after addition of TISAB buffer	3.9%	Orion 1977
Total dissolved solids	Fu	Evaporation	3.2%	

The standard deviation for the duplicates is obtained from the relation

$$\% S = \sqrt{\frac{\sum_{1}^N \left( \frac{2t_i}{t_{i_1} + t_{i_2}} \right)^2 - \frac{N}{N} \left( \frac{2t_i}{t_{i_1} + t_{i_2}} \right)^2}{N - 1}} \quad (1)$$

where %S=Precision (standard deviation on per cent basis).  
 t<sub>i</sub>: Result of a singular determination  
 t<sub>i<sub>1</sub></sub>, t<sub>i<sub>2</sub></sub>: Results of duplicate determinations of each sample.  
 N: Number of determinations.

For multiple determinations relation (2) was used

$$\% S = \sqrt{\frac{\sum_{1}^N t_i^2 - \frac{(\sum_{1}^N t_i)^2}{N}}{N - 1}} \quad (2)$$

The precision value obtained for magnesium (Table 1) is probably an overestimate in relation to the present samples, since several high temperature samples with very low magnesium concentrations were included.

The gas sample was analyzed with a Carle AGC 111 H,S gas chromatograph using a Poropak column to retain and separate H<sub>2</sub>O, CO<sub>2</sub> and H<sub>2</sub>S from the rest of the gas, and a Molecular Sieve 13X column at 75°C to separate H<sub>2</sub>, O<sub>2</sub> + Ar, N<sub>2</sub> and CH<sub>4</sub>. Nitrogen was used as a carrier gas for hydrogen detection, but helium for the detection of the others. Detection is by a thermal conductivity detector (Hauksson 1981).

The analyses for deuterium and oxygen-18 were carried out mass-spectrometrically by Dr. George Darling, Institute of Geological Sciences, Hydrological Division, Crowmarsh Gifford, Wallingford, Oxfordshire, England, and his assistance is fully acknowledged.

### 3 GEOTHERMAL RESOURCES

#### 3.1 General features

The temperature of the earth's crust increases with depth. Heat flows from the interior of the earth to the surface by means of conduction or mass transfer. Observations from various geological settings demonstrate a difference in heat flow, generally decreasing with age (Pollack 1982). The heat flow from Cenozoic volcanic areas can be, on average, twice as high as from Precambrian shields. Geothermal fields are areas where the geothermal gradient is abnormally high and a large amount of heat is transferred to the earth's surface usually by means of water circulation. Abnormally high heat flow to the surface is most obvious in regions of volcanic activity in the form of volcanic eruptions where molten lava extrudes and fumaroles and hot springs are numerous. Volcanic activity and associated geothermal fields are found in many parts of the world usually closely related to plate boundaries. Geothermal fields are found in areas where plates are being formed, such as in Iceland as well as in areas of plate subduction (New Zealand, Japan, Philippines). The anomalous geothermal gradient in such areas is usually caused by the intrusion of magma into the upper layers of the crust. The magma body cooling at a shallow depth causes a local high geothermal gradient, the ground water becomes heated and moves due to a reduction in density towards the surface where the heat is released into the atmosphere.

Besides the very high geothermal gradient around cooling intrusions at high crustal level, the regional gradient in certain areas can be sufficient for geothermal systems to form, provided that permeable strata or fractures allow deep circulation of groundwater, under a hydrostatic head. Upflow of warm groundwater and geothermal surface manifestations would in this case preferably be found along faults at topographically low levels. This type of geothermal system usually leads to lower temperatures than the former and is referred to as a low temperature area as opposed to a high temperature area.

### 3.2 Terminology

Surveys of geothermal energy utilization have been carried out at the request of the Technical Panel on Geothermal Energy of the Preparatory Committee for the United Nations Conference on New and Renewable Sources of Energy, Nairobi 10th - 21st August 1981 (Guðmundsson & Pálmason 1981, Bolton 1981). For the purpose of these surveys it was decided convenient by the Panel to use 180°C as the temperature limit dividing high and low temperature geothermal fields. This terminology will be adhered to in this report. High temperature areas are characterized by fumaroles, solfataras, mud pools and alteration of the surrounding rocks. They are usually connected with active volcanism. Low temperature areas are characterized by hot water springs and little alteration of the rocks. Of course, 180°C is no absolute limit and there exists a number of borderline cases.

### 3.3 Utilization

Geothermal water has been used by man for centuries for bathing, cooking and heating, but any further utilization has been minimal until quite recently. Geothermal power can now be used at a wide range of temperatures. Fig. 2 shows the approximate temperatures for various geothermal uses (Edwards et al. 1982). The utilization can be divided into two categories, direct and indirect. The former includes space heating and cooling, agriculture and agricultural production, and industrial processes. A recent study of the world's direct geothermal energy utilization shows that about 8000 MW thermal are installed in 11 countries (Guðmundsson & Pálmason 1981). The production of electricity is by far the most important indirect utilization of geothermal energy, and in 1980 the installed capacity for geothermally generated electricity was 2462 MW electric (Bolton 1981).

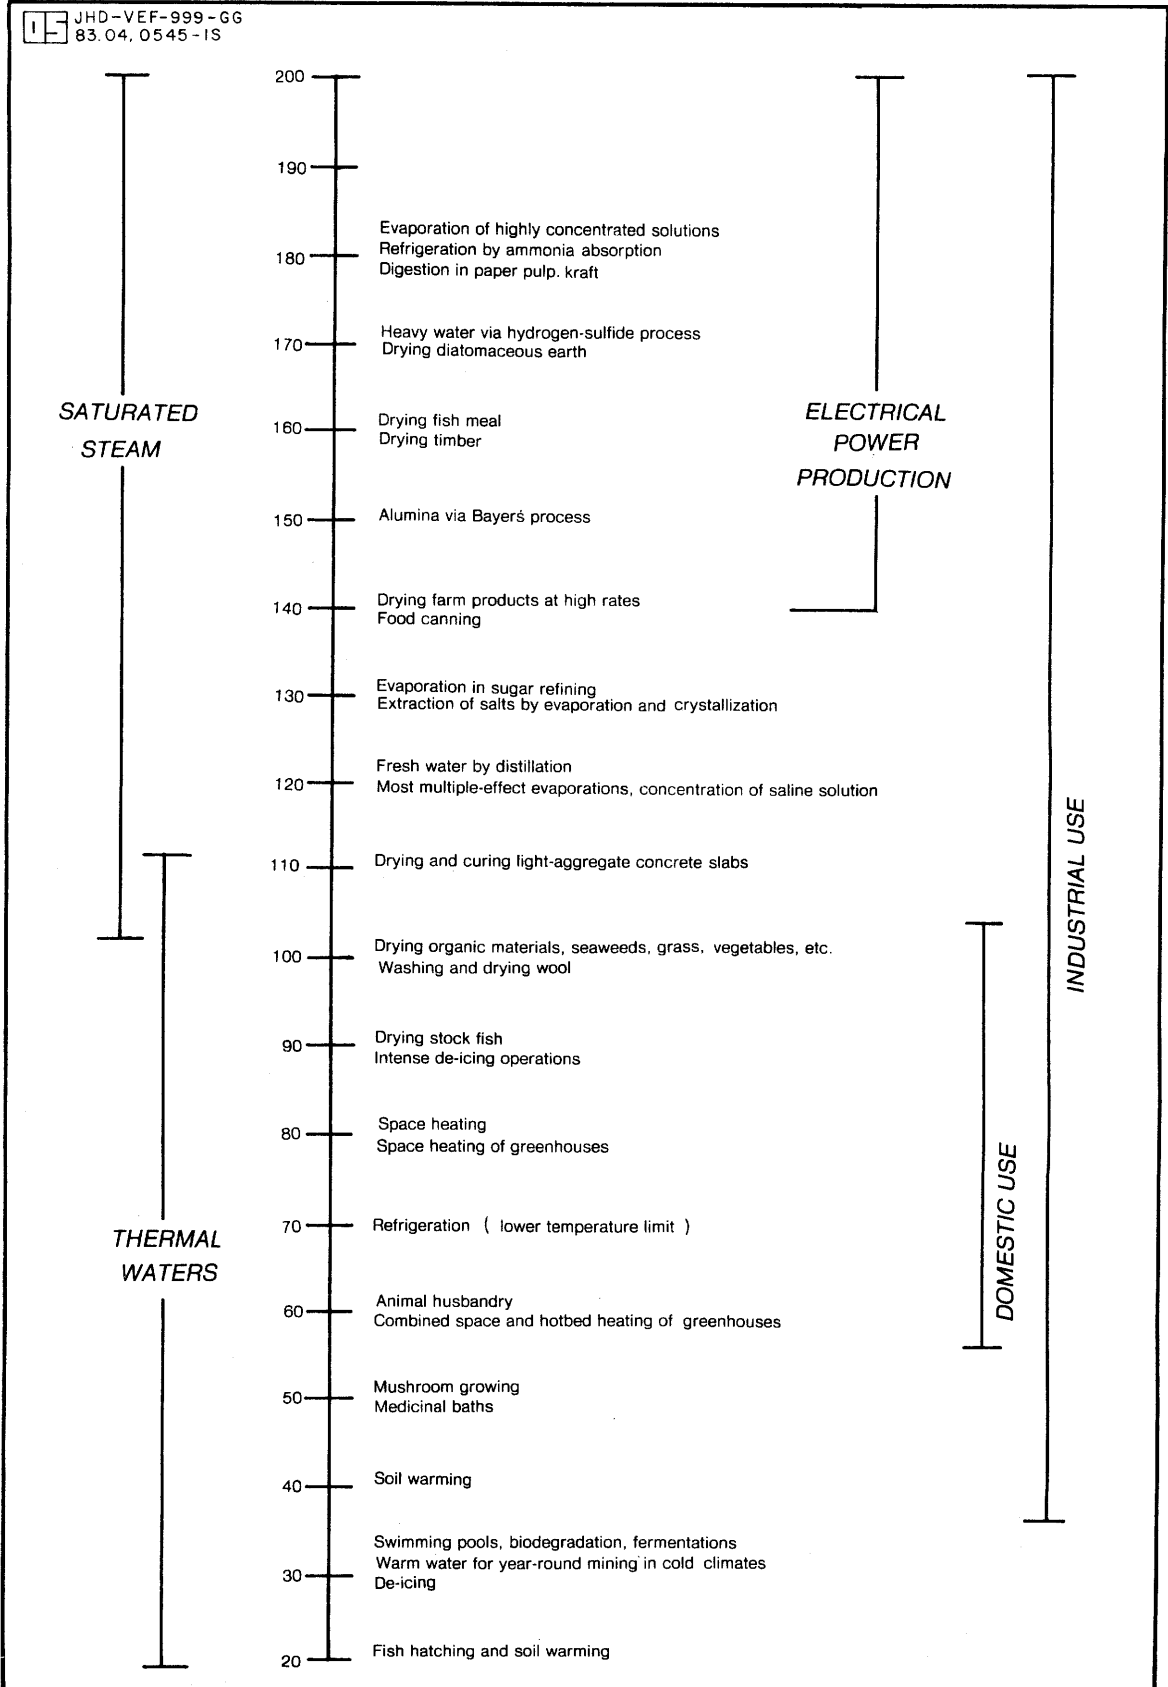

Fig. 2 Approximate temperatures for various geothermal uses

#### 4 THE ENERGY SITUATION IN BURUNDI. PRESENT STATE AND FUTURE NEEDS

Burundi is a landlocked country in central Africa. It has borders with Zaïre in the west, Rwanda in the north and Tanzania in the east and south. Its area is 27820 km<sup>2</sup> and its population 4.2 millions. The biggest city is the capital Bujumbura, with ca 150000 inhabitants. The main industry is agriculture and the major products are cotton, rice, tea and coffee. The income from coffee constitutes about 90% of that of the total export, so that Burundi's economy is very much dependent on the world coffee price. Industry is not extensive and mostly connected with agriculture, such as in textiles, tea and coffee.

The bulk of the information below was obtained at meetings with the people responsible for Burundi's energy sector, but it has been supplemented after consultation with the UNDP/World Bank report by Hughart et al. (1982) who surveyed the energy situation in Burundi. Details of energy sources and uses are listed in Table 2 and locations of energy plants and power transmission lines are shown in Fig. 3.

The major problems in Burundi's energy sector are the very extensive use of fuelwood, which is causing a very rapid dwindling in its supply, and the very high cost of petroleum products caused partly by last decade's rise in oil prices but also the high cost of transport. The most pressing needs are thus the reduction in the use of these two fuel types. Both high and low temperature geothermal areas could be useful in this respect. It is in the industrial use in the tea factories, the brewery and the textile factory, where at first glance it seems most promising to replace fuelwood or fuel oil by geothermal water or steam. Some household uses are feasible even though space heating is not in great demand. Hot water might be piped into homes, missions or farms for various uses. Several of the geothermal sources in Burundi have traditionally been used for bathing and some are renowned for their curative properties. These are generally large flow sources, where construction and running of pools would not present great problems. With the advent of tourism warm pools and health spas might be a valuable asset. Some of the thermal waters are carbon-dioxide rich.

TABLE 2 Burundi 1982. Energy sources (present and planned) and their uses

Energy source	Location	Stage	Production	Chief uses	Notes
Agricultural and forestry resource base (Forests, savannah, fuelwood agricultural residues)	All over		Reputed to be ca 90% of all energy consumption	Rural and urban households (Cooking, heating, lightning) Tea factories, Missions	Includes charcoal production, chiefly for urban households
Peat	Akanyaru Basin Nyamuswaga Highland (Kishubi, Kitanga, Nyacijima, Kashiro, Kurunyange)	Early development	10.000 tns/year estimated for 1982. (1981: 6.000 tons)	Tea factories Missions	Estimates range from 100-1500 million ton resources
Hydro-electricity	Rusizi I.	Complete	Total 28 MW Burundi 9 MW	Urban households. Urban industrial/commercial (lighting, electrical appliances etc.)	Imported from Zaïre
	Mugere	- " -	8 MW		
	Rwegura	Under construction Expected to be completed in 1986	18 MW (planned)		Imports from Zaïre will discontinue, when completed etc.)
	Rusizi II	Planned. Construction expected to start 1983	Total 40 MW planned. Burundi's share uncertain		EGL project with Rwanda and Zaïre
	Rusumo Falls Rwanda	Under study	Total 60MW planned, Burundi's share uncertain. Could be 20-70 MW according to design.		Cooperation project with Uganda, Rwanda and Tanzania. Tanzania's interest deciding factor
	Gitega	Just completed	1.2 MW		Germany supervised construction REGIDESO about to take over

Both use primarily fuel oil

FIG. 3. BURUNDI: POWER PLANTS AND TRANSMISSION LINES

Such natural mineral water is by many regarded as a health drink, and its bottling could become a minor source of income.

An overview of the electricity situation in Burundi is presented in Table 2 and it is summarized in Table 3 making the following assumptions:

- That Burundi's share of the production from the Rusizi II plant will be one third.
- That a 60 MW plant will be constructed at the Rusumo Falls in Rwanda, and that Burundi's share of its production will be a quarter.
- That the diesel-driven generators in Bujumbura will be rehabilitated.
- That Burundi will cease to buy electricity from the Rusizi I plant, when the Rwegura plant starts producing.

In their report Hughart et al. (1982) assume that the growth in demand for electrical power will remain at 10-11% per annum during the 1980s. This is considerably lower than the government's estimate, but even at that rate all planned electricity plants and those under study would only just manage to satisfy this demand in 10-11 years time, if successfully completed by then. The future energy situation thus needs serious consideration. Electricity would, however, not be produced from geothermal resources unless high temperature areas were found.

TABLE 3. Burundi 1982. Electricity production, present and planned (MW)

Plant Types	Present		Planned		Total, when all projects finished	Need in 10-11 years, assuming 10-11% growth per year.

Diesel-driven		4,7	6		10,7	
Total	9	15,2	39	15	69,2	69

## 5 BURUNDI: GEOLOGY AND GEOTHERMAL FEATURES.

### 5.1 Geological information

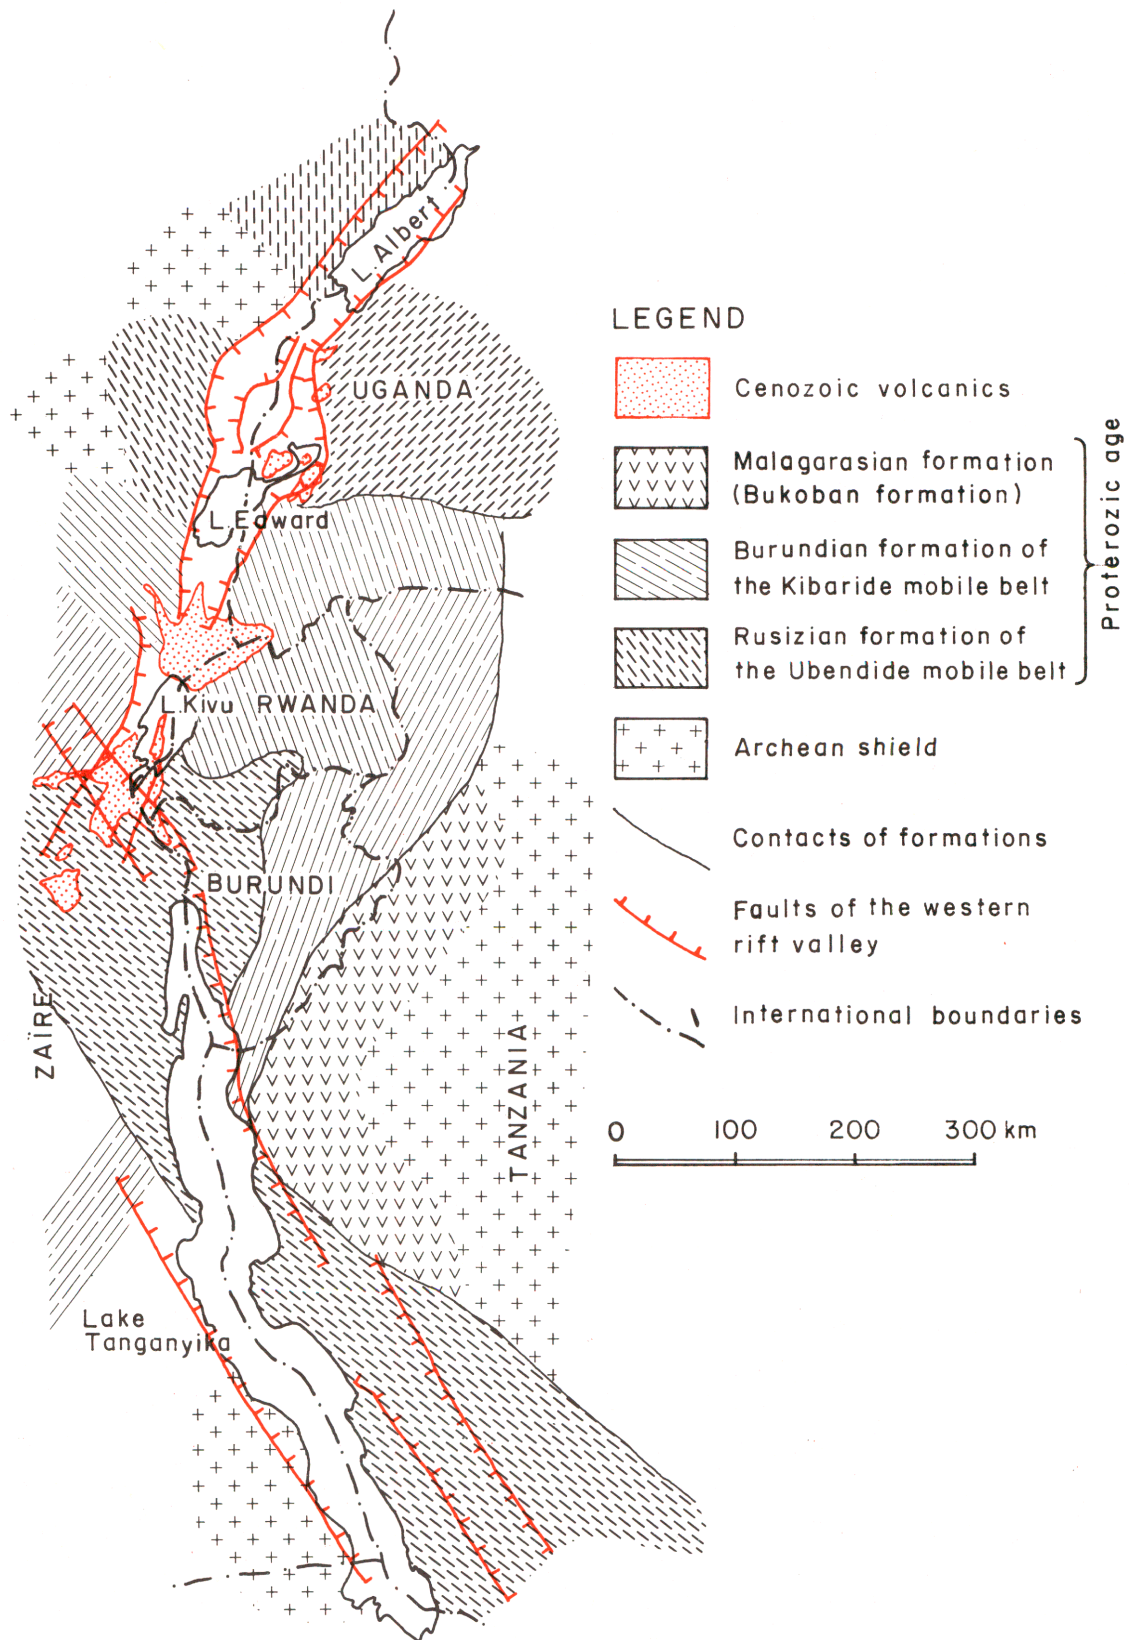

The structure of East-Africa away from the rift zone is typical of stable shield areas. The base rock is of Precambrian age and can be described as granitoid shields of Archean age flanked by metamorphic rocks of Proterozoic orogenic belts (McConnell 1972). One of the shields is the Tanganyika shield of Tanzania which has a minimum age of 3000 m.y. The shield is flanked in the west and south by the Ubendide, Kibaride and Bukoban orogenic belts (Fig 4). Burundi is west of the Tanganyika shield and its oldest rock formation is the Rusizian of the Ubendide belt, whose age is in the 2000 to 1600 m.y. range. The Burundian belt of the Kibaride formation overlies unconformably the Rusizian. Its age is in the 1300-1000 m.y. range. The Malagarasian lies unconformably on the Burundian. This formation which is a continuation of the Bukoban formation of Tanzania seems to be formed outside the orogenic belts and is therefore less folded than the older formations. The age of this formation is 900-500 m.y. Many types of rocks are found within these formations, such as quartzite, which seems to be the most common, schist, dolomite, sandstone, conglomerate, phyllite and intrusive rocks such as gabbro, dunite, serpentinite and granite.

The rift system is a much younger structure in the geology of East-Africa than the formations described above. It extends over 6500 km from Turkey to Mozambique and includes the Dead Sea, the Red Sea, the Gulf of Aden, and the East African rift which is divided into two branches, the eastern and western rifts, separated by the Tanzanian shield. The rifts frequently run parallel to the Precambrian mobile belts. The western rift runs for instance parallel to the Ubendian and Rusizian fold belts. Some authors believe that the rifts originated in the Precambrian era and that they have been reactivated several times (McConnel 1972).

Seismic and gravimetric studies suggest that a significant

The principal geological structures of central Africa

thinning of the crust occurs in the rift zones (Long et al. 1972, Darracott et al. 1972, Baker et al. 1972). The nature of the zones indicates a magmatic mechanism similar to those underlying the mid-oceanic ridges, although no new oceanic crust has been formed in the intracontinental rift of East Africa.

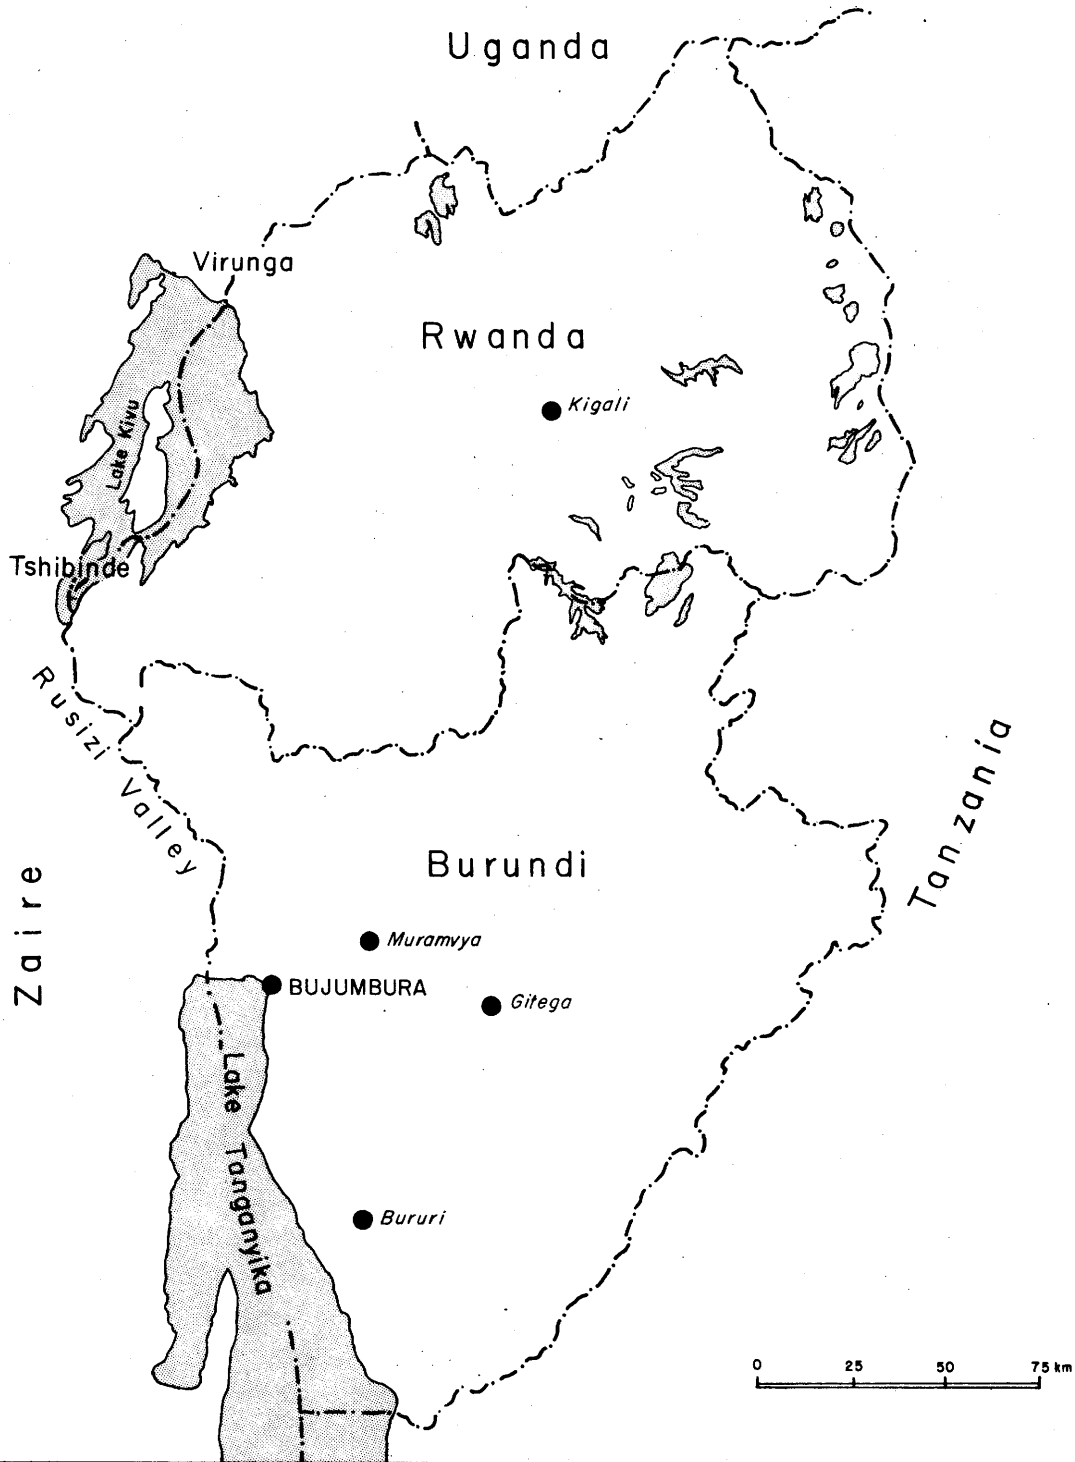

The East African rift system is of Cenozoic age (McConnel 1972) and is still active as numerous active volcanoes and seismic activity show (Fairhead & Stuart 1982, Williams 1982, Barberi et al. 1982). The floor of the western rift valley is usually covered with young sediments. In the Lake Albert region the thickness of the sediments is 2.5 km and close to 1 km in the Albert Nile sector (Williams 1982). The sediments can form a good geothermal reservoir, whereas the Precambrian rocks are considered very poor in this respect.

Heat flow in the rift is anomalously high although not as high as in the oceanic ridges. Anomalous heat flow is not found on a regional scale in the western rift but is limited to areas or nodes where strikes cross or change direction (McConnel 1972). Heat flow studies suggest relatively low values for Lakes Malawi and Tanganyika although high local values can be found there. In Lake Kivu a wide range of heat flow has been found (Degens et al. 1973, Morgan 1982). An intense volcanism is known in the eastern rift. In the western rift volcanism occurs at fewer localities near rift culminations at rift arms junctions (McConnel 1972, Barberi et al. 1982). The volcanic zones are Rungwe, South Lake Kivu, Virunga and Toro-Ankole (Fig. 4 & 5). The alcalic composition of the rocks indicates great depth of magma generation below both rifts.

Burundi lies east and north of Lake Tanganyika. It is situated astride the eastern margin of the western rift. The Burundian coast of Lake Tanganyika and the Rusizi valley belong to the rift. This part of the country is considered to have the highest heat flow and is therefore the most probable area of potential geothermal resources. There are no active volcanic areas in Burundi, but the South Lake Kivu volcanic area is just north of the borders in Zaire and Rwanda (Fig. 4). It is located on the intersection of the NW-SE trending part of the rift (Lake Tanganyika) and the NE-SW trending part (Lake Kivu to Lake

JHD-JEF-9000-GG  
83.04.0563-IS

Fig. 5. Burundi and neighbouring countries

Albert). The volcanic activity is clearly related to the fissure system. The area is divided into two separate fields, the Mwenga-Kamitunga, which lies outside the intersection, and the Tshibinde zone just south of Lake Kivu (Guibert 1977 a, b, Barberi et al. 1982). The lavas are basanites, alkalibasalts, and transitional quartz and olivine-tholeites, tholeites being very rare elsewhere in the East African rift system (Williams 1982). The age of the volcanic activity is uncertain but seems to range from late Cretaceous (70-90 m.y.) to present. The youngest reported eruption occurred during the last century (Guibert 1977 a,b).

## 5.2 Summary of previous geothermal research in Burundi

The first description of geothermal manifestations in Burundi was given by Stanley (1878), but the first specific investigation of geothermal activity in the country was carried out in 1968 by the UNDP following a request from the Burundian government (McNitt 1969). This study covered eight geothermal locations. The geology of their surroundings was described, and a geochemical examination of the discharges recommended. Deelstra et al. (1972) described 15 hot springs in Burundi, 1 in Rwanda and 3 in Zaïre. Results of chemical analyses of 9 Burundian, one Rwandan two Zaïrian geothermal water samples were reported. Edeline et al. (1981) described 14 geothermal locations and reported chemical analysis of samples from 13 of them.

All these reports concentrate on descriptions of the thermal sources and their immediate surroundings. The geothermal activity is mostly connected with faults in Precambrian rock or sediments. There is no record of a connection between recent volcanism and geothermal activity even though one of the geothermal locations is in an area of basaltic formations according to the geological map edited by Radulescu (1981). Little attempt is made to relate the existence of geothermal heat to the general geology of the country. It is, however, clear that all the sources are situated in the western or central parts of the country and none in the eastern part where intrusions are absent and which lies farthest away from the active

rift zone.

All reported geothermal sources in Burundi are water pools. There is no record of surface steam (fumaroles) or mud pools. Therefore it seems unlikely that high temperature geothermal areas will be found there. The highest recorded geothermal spring temperature is 68°C at Ruhwa (Fig.1) (McNitt 1969, Deelestra et al. 1972, Edeline et al. 1981). Application of the quartz geothermometer of Fournier & Rowe (1966) to the results of Deelstra et al. (1972) and Edeline et al. (1981) suggests underground source temperatures as high as 110-120°C in at least two places in the Rusizi Valley.

6 THE RESULTS OF THE NEA RECONNAISSANCE MISSION  
1982.08.30 - 09.13

6.1 Descriptions of geothermal manifestations

This chapter contains short descriptions of all the geothermal locations visited during the present study. It is not possible to make an in depth geological study while on a short field trip and detailed geological maps were only available of two of the sites (Lepersonne 1977). Geological descriptions are therefore rather meagre.

**Kabezi:** The area is about 20 km south of Bujumbura, on the eastern bank of Lake Tanganyika. The thermal water rises through uncemented lake sediments in 4 pools each less than 1 m in diameter. The pool sites are obviously controlled by a linear structure, perhaps one of the faults which form the eastern escarpment of the rift valley. The slope to the east of the valley starts rising a few hundred metres to the east of the springs and the trend of the escarpment is similar to that of the structure controlling the direction of the observed spring sites. The hot water flow is difficult to estimate because no run-off stream is formed, but the water seeps through the surface soil towards the lake. The maximum temperature is 38.0°C in the main spring but values ranging from 34.0 to 37.7°C were recorded in the other three. No gas flow was observed nor were there any signs of deposits.

**Mwisale:** The village Mwisale is situated in the mountain range which forms the eastern escarpment of the western rift about an hour's drive from Bujumbura. The village lies in a deep valley and a noticeable feature was a considerable water flow through all gullies running into the valley even though the field trip was made late in the dry season. This indicates that the rainwater is able to penetrate into the Precambrian rock. This permeability is higher than expected and could be caused by Tertiary and Quaternary faults related to the formation of the rift. The geothermal source is found high up on a slope to the south of an E-W trending valley close to a contact between schist and

quartzite. Three springs were found and the estimated total flow is 10-20 l/s. The temperature of the main spring is 37.0° C, but 31.6 and 36.2°C were recorded in the other two which are slightly to the west of it. All the springs lie in a NNE-SSW trending gully which apparently is controlled by a fault. No gas flow was observed but deposits of iron compounds are found on stones in the springs.

**Mashuha:** The Mashuha spring is situated at the foot of a low quartzite hill of Precambrian age. The water flows from a small pool in which a considerable gas flow is observed. Its temperature is 37.7°C and the flow was estimated at 10 l/s. The pool is used by local people for laundering and bathing. No obvious connection with fractures or faults was to be seen, and this manifestation is the one in Burundi which is farthest away from the western rift.

**Mvumvu:** The Mvumvu spring is situated close to the main road from Bujumbura to Kigali via Muramvya. The thermal water flows into a small pond in a valley covered with sediments. The area is covered with vegetation, but the water probably rises through syenite. The temperature is 28.5°C and the flow close to 5 l/s. Very little gas flow was observed. The spring is used for laundering. No linear structures to which geothermal manifestations could be related were observed. The distance to the rift valley is 20-30 km so a connection with young tectonic structures must be considered unlikely.

**Mahoro:** The Mahoro spring lies in a small valley which is covered with vegetation. The hot springs form a pond about 10 m in diameter. The upflow is clearly controlled by a linear structure because small outflows of water accompanied by considerable gas flows were observed forming a line on the bottom of the pond. A steeply dipping quartzite outcrop whose strike is parallel to the line of the springs is situated close to the pond. Joints in the dipping rock formation are more likely to control the upflow of warm water than young tectonic structures. The temperature is 45.0°C and the flow estimated at 8 l/s. This warm water is believed to have healing effects on those who bathe in it and is to a considerable extent used for this purpose.

**Kitenge:** The geothermal manifestations are found in the

deep valley of the river Kitenge. The area is very mountainous and it is a part of the uplifted eastern margin of the rift valley. The water flows from cracks in the quartzite which seems to be the dominant rock type. Warm water is also found in the alluvium. This is also a gold panning site. Many shallow holes have been dug in the sediment for this purpose and some of those are now full of warm water. At least 3 springs were found discharging from the quartzite. The temperature of the warmest one was 47.1°C, and its flow 4 l/s. The area lies in the uplifted mountain range bordering the rift. Thus relatively young faults could exist there. The terrain, however, is difficult and it proved impossible in the short time available to investigate in detail the possibility of a connection between the hot springs and young faults.

**Mabayi:** The hot water flows from the river Nyamagana alluvium. The rock formation cannot be seen because of the vegetation covering it. The manifestations are situated in a sugar cane field and form a little pool on the river bank. Some gas flow was observed. The flow was estimated at 7 l/s, and the temperature recorded was 37.7°C. Springs were observed on the bottom of the river, where a temperature of 37.9°C was recorded and gas bubbles were seen rising. Another spring is reported to be situated on the other side of the river, but this was not visited. The manifestations lie on a line trending N6°E and are controlled by a fault or a syncline.

**The Rusizi valley:** The part of the western rift valley which lies between Lake Tanganyika and Lake Kivu is called the Rusizi valley taking its name from the river flowing through it. The floor of the valley is filled with young sediments, although low hills made of older rocks are found within the rift. At least four geothermal locations are known in the Burundi part of the Rusizi valley all of which were visited during this study: the Ruhwa, Ruhanga, Gasenyi and Cibitoke sites.

**Ruhwa:** The hot spring is located on the bank of the river Lua about 100 m upstream from where it meets the Rusizi. The Lua serves as the border between Burundi and Rwanda and the Rusizi as the border between Burundi and Zaire. The water rises from the top of a small travertine elevation, about 20 m in diameter and 4-5 m high. The thermal spring

is in a pool which has a 2-2.5 m diameter, and through which there is a violent gas release. Its temperature is 63°C and its flow 1 l/s. The area is covered with vegetation but the site is shown within a Tertiary basalt formation on the geological map edited by Radulescu (1981). Furthermore basalt has been reported in a nearby drillhole (Deelstra et al. 1972).

**Ruhanga:** The manifestation is right on the Rusizi bank in the alluvium. It is probably flooded during the rainy season. The floor of the valley is covered with sediments consisting mainly of quartzite cemented with carbonate. The river has eroded a channel, about 20 m deep, into the sediments, and the alluvium is composed of pebbles of quartzite and basalt. The source is a small pool with a very small flow, whose temperature is 48.3°C. Few signs of deposits were observed.

**Gasenyi:** This location is very similar to that of Ruhanga, but here the outflow of warm water is in the river itself. It proved impossible to measure the flow but some gas flow was observed. Gas bubbles were seen in the river as far as 3 m from the bank. The highest recorded temperature 59.5°C was on the river bottom, but highest on shore was 49.6°C in a small pool from which the sample for chemical analysis was drawn (See section 6.2).

**Cibitoke:** This hot spring is the only one in the valley which is not situated on the Rusizi river bank. It is on the flat floor of the valley, hidden in a field of very tall grass. The surface manifestation is a pool about 1 m in diameter and at least 2 m deep. It is difficult to estimate the flow, but it could be 4-5 l/s, and the temperature is 30.6°C. The water in the pool was muddy and violently agitated by the rapid escape of gas.

The four locations of surface geothermal activity in the Burundi part of the Rusizi valley are all found within the sedimentary formation. It is difficult to see whether their locations are related to young faults or other structures, but their occurrence within the still active rift zone and the relatively short distances between the manifestations could indicate a high geothermal gradient in the Rusizi valley.

**Mugara:** The Mugara springs are all within the rift valley even though the water rises through Precambrian quartzites. Mugara I and II are separated by a few hundred metres and are situated in a small hollow. The water rises from fractures in the rock and temperatures and flows were recorded as 46.8°C and 20 l/s; and 44.8°C and 10 l/s for Mugara I and II respectively. Mugara III is located about 1 km north of the above springs. Here the hot water rises in several springs in a relatively flat landscape, where there is dense vegetation. Its temperature was recorded as 46.0°C and flow estimated at 20 l/s. Iron oxide deposits were observed at all three locations, but no gas flow was observed. Vegetation made it difficult to determine whether the geothermal activity is controlled by faults or other structures but the geological map available (Lepersonne 1977) shows the main fault of the eastern escarpment of the rift only 1-2 km east of the springs, and a fault possibly runs through the Mugara sites.

**Kumuyange:** Two springs, separated by 2-300 m rise from Precambrian quartzite. Walls have been built around the main springs and the water is used by local people for bathing. The temperature of the more southern (western) spring was recorded as 38.4°C and its flow as 3-4 l/s. Some gas flow was noticed. There is no knowledge of structural control of the springs but the site is clearly outside the rift valley.

**Muhweza:** This manifestation is rather similar to Kumuyange. The water rises from fractures in quartzite in two springs, separated by some 50 m. Both are used for bathing. The temperature was recorded as 37.3°C but the flow is not known. Gas flow is minimal. The Muhweza springs lie about 8 km east of Kumuyange and a connection with the rift zone is not likely.

**Cold water sample sites:** Three samples of cold water were collected for reference during the study. The first spring sampled rises through the Rusizi valley sediments at Nyakabaraza close to Cibitoke. Its temperature was 22,7°C. The second cold water sample was drawn from Source du Nil, east of the rift valley in Precambrian rock. Its temperature was 16.8°C. The last cold water sample was collected from Lake Tanganyika from the shore in the southern part of Bujumbura. Its temperature was 28.0°C.

## 6.2 Results of chemical analysis

Results of the chemical analysis of the water samples are reported in Table 4, of the gas sample from Ruhwa in Table 5 and the isotope analysis in Table 6. Speciation, mineral composition, and deep water composition at the quartz temperature were calculated using the WATCH 3 computer programme (Arnórsson et al. 1982, Svavarsson 1981). The resulting printouts are in Appendix 2. As a first approximation it may be noted that the samples from the rift valley have a higher pH, are more mineralised and have greater carbon dioxide concentrations than those which originate from the Precambrian rock. These results will be looked at in more detail in the following sections.

## 6.3 Chemical geothermometers

These are generally of two types, i.e. those based on the solubility of species e.g. silica, and those based on concentrations of constituents resulting from exchange reactions, e.g. alkali and alkaline earth metals. The solubility of silica is controlled by the mineralogy. At high temperatures ( $>150^{\circ}\text{C}$ ) it is generally quartz which controls the solubility but in some cases, especially in young formations, minerals such as chalcedony or even cristobalite may become effective at lower temperatures. Thus the chalcedony thermometer has proved quite useful in Iceland (Arnórsson et al. 1983). In Burundi, however, the situation is quite different. Rock formations are relatively old and the chief silica mineral observed is quartz. It seems reasonable to assume that the quartz geothermometer is the one that should give the results for underground temperatures which most closely approach the true ones, even at temperatures well below  $150^{\circ}\text{C}$ . At temperatures below  $80^{\circ}\text{C}$  the increase in silica concentration with increasing temperature is relatively small and it may be difficult to use this chemical geothermometer to obtain an accurate source temperature. At  $100^{\circ}\text{C}$ , this increase has become very significant (Fig. 6).

The solubility of quartz in the temperature range  
25-300°C as a 3 phase curve  
Quartz-water-steam

The most commonly used exchange thermometers are based on the sodium/potassium ratio. The Na-K-Ca geothermometer (Fournier & Truesdell 1973) takes exchange reactions involving calcium into account and the Na-K-Ca-Mg geothermometer (Fournier & Potter 1979) adds a correction for magnesium concentrations. As a result of a survey of geothermometers it was decided to calculate and base the estimation of underground temperatures on the following chemical geothermometers:

1) Quartz. The equation due to Fournier & Rowe 1966:

$$t^{\circ}\text{C} = \frac{1309}{5,19 - \log C_{\text{SiO}_2}} - 273,15 \quad (1)$$

where  $C_{\text{SiO}_2}$  =  $\text{SiO}_2$  concentration in mg/kg water has been modified to

$$t^{\circ}\text{C} = \frac{1309}{0,41 - \log [\text{SiO}_2]} - 273,15 \quad (2)$$

where  $[\text{SiO}_2]$  = mole  $\text{SiO}_2$ /kg water is calculated as free  $\text{SiO}_2$  present in  $\text{H}_4\text{SiO}_4$ , i.e. available  $\text{SiO}_2$

2) Chalcedony (Arnórsson et al. 1983)

$$t^{\circ}\text{C} = \frac{1101}{0,11 - \log [\text{SiO}_2]} - 273,15 \quad (3)$$

where  $[\text{SiO}_2]$  = concentration of available  $\text{SiO}_2$  in moles/kg water (computed activity of  $\text{H}_4\text{SiO}_4$  ).

3) Na-K-Ca-Mg (Fournier & Potter 1979)

The Na-K-Ca temperature is calculated

$$t^{\circ}\text{C} = \frac{1647}{\log([\text{Na}]/[\text{K}]) + \beta \log(\sqrt{[\text{Ca}]/[\text{Na}]) + 2,24} - 273,15 \quad (4)$$

where [ ] = concentration of metal in moles/kg

$\beta = 1/3$  for temperatures  $> 100^{\circ}\text{C}$

$\beta = 4/3$  for temperatures  $< 100^{\circ}\text{C}$ .

The magnesium factor ,R, is calculated as

$$R = \{ [\text{Mg}]/[\text{Mg}] + [\text{Ca}] + [\text{K}] \} \cdot 100 \quad (5)$$

where [ ] = concentration in moles/kg. If  $R > 50$ , the water is assumed to come from a relatively cool underground environment at a temperature approximately equal to the measured water temperature, irrespective of high calculated Na-K-Ca temperature. If  $t_{\text{Na-K-Ca}} > 70^{\circ}\text{C}$  and  $R < 50$ , use Fig. 7 to estimate the magnesium temperature correction,  $\Delta t_{\text{Mg}}$ , to be subtracted from  $t_{\text{Na-K-Ca}}$  drawn from the following equation

$$\begin{aligned} \Delta t_{\text{Mg}} = & 10,66 - 4,7415R + 325,87(\log R)^2 - 1,032 \cdot 10^5 (\log R)^2 / T \\ & - 1,968 \cdot 10^7 (\log R)^2 / T^2 + 1,605 \cdot 10^7 (\log R)^3 / T^2 \end{aligned} \quad (6)$$

The results of the application of the above three geothermometers to the Burundi samples are listed in Table 7 along with measured temperatures and likely source temperatures which are estimated from the geothermometer results after taking the following considerations into account.

- As the Na-K-Ca-Mg geothermometer does in several cases yield values which are lower than measured temperatures it is assumed that its application generally leads to slight underestimates.
- Quartz is the major silica mineral, but it is the most soluble of the ones which could possibly be present. Hence the quartz geothermometer is likely to give maximum values if it is assumed that no boiling or mixing with cold groundwater has occurred in the upflow zone or the reservoir.
- On the same grounds application of the chalcedony geothermometer is likely to lead to values below the actual underground source temperatures.
- Quartz temperatures below 80°C are inaccurate.
- Some individual cases are discussed below.
- The results for Mabayi are obviously too low, being below the measured temperature. However, these low results suggest strongly that the underground source is not much warmer than the surface outflow.
- The Na-K-Ca-Mg temperatures for Ruhwa (34°C) and Ruhanga (37°C) are obviously much too low, measured temperatures (63°C and 48°C respectively) being considerably higher. The quartz temperatures (109°C and 120°C) seem likely to be closest to the truth in these cases.

The highest estimated underground source temperatures are for Gasenyi, probably >100°C, and Ruhanga and Ruhwa, probably similar. Furthermore the Gasenyi sample source is right on the Rusizi river bank, virtually in the river, and its temperature was 49.6°C, even though a temperature of 59.5°C was recorded on the river bottom only a couple of metres away. Therefore it is almost certain that this sample source was mixed with cold water. The Gasenyi, Ruhwa and Ruhanga springs are all found in uncemented recent sediments which makes mixing with local cold groundwater in upflow zones likely.

No samples were actually taken from the rivers Lua and

TABLE 7 Burundi 1982. Measured temperatures, chemical geothermometer temperatures and probable source temperatures.

Rusizi, but the water from Nyakabaraza is assumed to be representative of the cold water of the region. Using Fournier's (1977) mixing models the results reported in Table 8 were obtained for possible temperatures of unmixed underground geothermal fluids for the cases of cooling without boiling and boiling with maximum steam loss. Boiling is likely to have occurred, although not necessarily with maximum steam loss. The lower values are therefore probably closer to the true ones than the higher values.

TABLE 8 Burundi 1982. Gasenyi, Ruhanga, Ruhwa. Results of mixing models. Cold water source: Nyakabaraza

Location	Underground source temperature assuming no boiling, °C	Underground source temperature assuming maximum steam loss, °C
Gasenyi	240	160
Ruhanga	220	150
Ruhwa	140	130

The results of the geothermometer study indicate that the reservoir temperatures are not high enough at most of the locations for them to be of commercial interest. The only exception are the springs in the Rusizi valley below which a reservoir with a temperature in excess of 100°C. may exist.

#### 6.4 Carbon dioxide rich discharges

Barnes et al. (1978) have defined a CO<sub>2</sub>-rich discharge as that of a gas containing more than 90 per cent CO<sub>2</sub> by volume by chemical analysis or water with pH less than 8.3 containing > 1000 mg/l bicarbonate. Arnórsson & Benjamínsson (1980) consider these limits as high and suggest that waters containing more than 300 mg/l CO<sub>2</sub> should be considered CO<sub>2</sub>-rich. By all definitions the waters from Kabezi, Ruhwa, Ruhanga and Gasenyi can be considered as CO<sub>2</sub>-rich, with the water from Cibitoke being close to it also. The gas from Ruhwa also qualifies (Table 5). Barnes et al. (1978) point out that CO<sub>2</sub>-rich discharges and seismic epicenters are concentrated mainly along or near the boundaries of major crustal plates, and probably result from the interaction of the plates. It is along these active plate margins that the resistance to plate motion is expressed as seismic energy and anomalous temperatures. Here, conditions are appropriate for the release of CO<sub>2</sub> from marine carbonate bearing rocks through processes of subduction and igneous intrusion. In addition fractures extending to sufficient depth may also yield CO<sub>2</sub> from the mantle. Attempts at distinguishing between these two source types are mainly made by studying the <sup>13</sup>C concentration in the CO<sub>2</sub>, as marine carbonate derived CO<sub>2</sub> is considered to have a <sup>13</sup>C concentration of ca 0 ‰ (SMOW), but mantle derived CO<sub>2</sub> -4 to -8 ‰. There is a possible overlap, but some useful information might be obtained by studying this parameter. Degens et al. (1971) found δ<sup>13</sup>C = 0 in CO<sub>2</sub> from Lake Tanganyika. The presence of these CO<sub>2</sub>-rich discharges enhances the possibility of finding high-temperature sources, as it suggests proximity with active magma sources.

#### 6.5 Calcite saturation

Areas with high carbon dioxide concentrations are the most likely to be troubled with calcite deposition in fissures. In the dilute waters undersaturation with respect to calcite is to be expected, but saturation or slight supersaturation in the more mineralized CO<sub>2</sub>-rich

waters. Severe supersaturation is not expected, unless the water has recently boiled and has not yet reequilibrated.

The ionic product  $[Ca^{++}] [CO_3^{--}]$  at the quartz temperature has been calculated for all the geothermal samples and the results are compared with the saturation curve (Helgeson 1969) in Fig.8. As expected most of the dilute waters are undersaturated. The Cibitoke and Mabayi waters are close to saturation, the Kabezi water slightly supersaturated, but the Mvumvu, Ruhanga, Ruhwa and Gasenyi waters are considerably supersaturated. When mixing models were considered, it was indicated that the latter three waters may have undergone boiling (see chapter 6.3), and the present result seems to support this. Boiling was not suggested in the other  $CO_2$ -rich waters, i.e. from Kabezi and Cibitoke, and the small supersaturation in Kabezi probably results from a relatively fast supply of  $CO_2$ .

## 6.6 Chloride concentrations and their distribution

Chloride in geothermal systems may originate from several types of sources, i.e. leaching of rocks or deposits, from rainwater, or percolating sea water. But once its concentration is established, it is relatively unaffected by changes in temperature and pressure as it does not participate in the formation of secondary minerals, and its contents in the water are controlled by the available supply. It is thus often a useful parameter in tracing geothermal water masses, whose chemical composition is otherwise affected by physical conditions, especially in conjunction with other constituents, similarly unaffected.

High chloride concentrations are often indicative of high temperature hot-water systems (White 1970). Such concentrations are then generally much above the chloride concentrations of nearby surface and ground waters. The area including Ruhanga, Gasenyi and Ruhwa (and possibly Kabezi) (Fig.9) shows the characteristics of such a system the effect being clear when the chloride concentrations of samples from these spots are compared with that of the sample from Nyakabaraza, which is regarded as a typical cold groundwater sample from the area. The variation of

### BURUNDI

#### Calcium carbonate ionic products and saturation curve

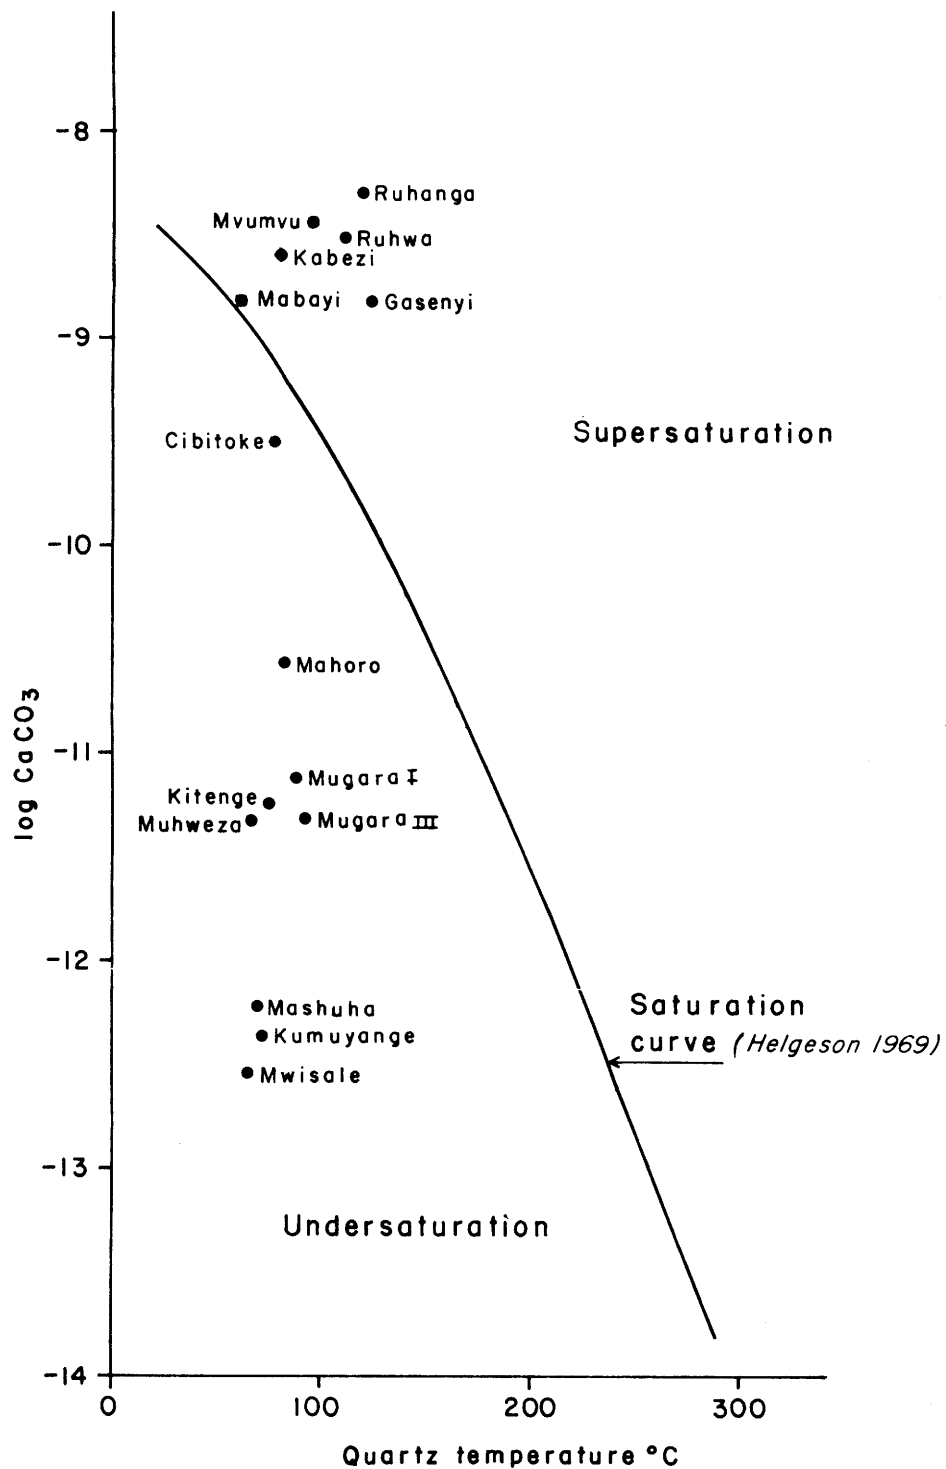

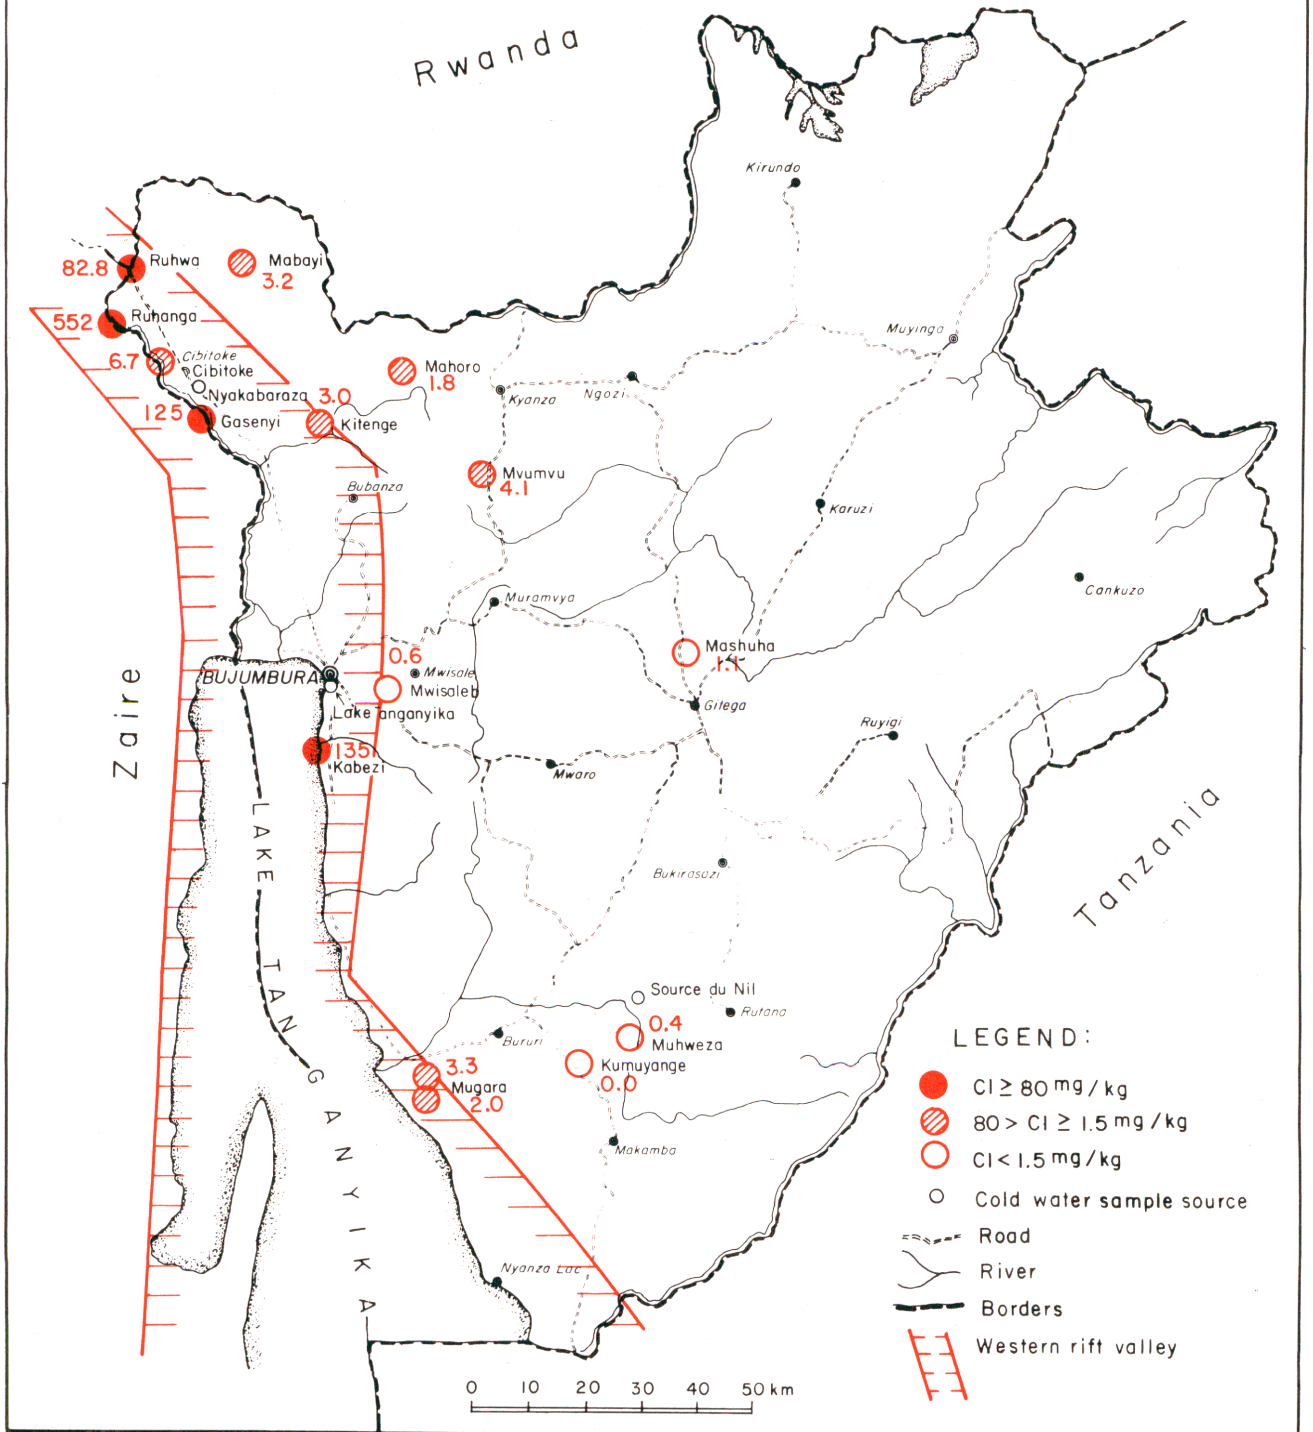

Fig. 9. Burundi 1982 CI distribution

chloride concentrations within an already established hydrothermal system can also give valuable information. Thus relatively high chloride concentrations indicate a permeable zone with flow from deep levels to the surface.

It may be argued that in some sedimentary environments chloride will be leached, and that this could account for the high concentrations of chloride in the Rusizi area. The low chloride concentrations in the Cibitoke and Nyakabaraza samples would seem to refute this.

Even allowing for differential dilution with cold water, the highest chloride concentration is at Ruhanga, and thus it would seem that there is the most direct connection with the deep reservoir (see Mahon 1970). The origin of the chloride may, however, be different in which case the last statement is not valid. Na/Cl ratio has sometimes been used to get an idea about whether water has a geothermal origin. High ratios usually indicate geothermicity. It is probably not very valid here, both because sea water effects in the rainwater are probably minimal, and some of the waters are CO<sub>2</sub>-rich, and this may modify their cationic composition.

Looking at Table 9 and Fig.10, however, relatively high Na/Cl-ratios are found in most of those places where the highest temperatures are indicated by the geothermometers described above, with the notable exception of Ruhanga.

Highest  $\text{Cl}/(\text{HCO}_3^- + \text{CO}_3^{--})$  (here reported as Cl/CO<sub>2</sub>) in related waters should indicate highest subsurface temperatures (Fournier & Truesdell 1970). Inspection of Table 9 and Fig.11 suggests highest subsurface temperature in the Rusizi area at Ruhanga on these grounds.

## 6.7 Fluoride concentrations

Fluoride is usually present in thermal waters at much higher concentration levels (commonly in the range 1-10 mg/kg (Ellis & Mahon 1977)) than are common in cold waters. Concentrations of this magnitude are found in samples from Kabezi, Ruhwa, Ruhanga, Cibitoke and Gasenyi (Fig.12), but also from Nyakabaraza, so that this is not an infallible

guide. Some of the other waters are very dilute, so a low absolute concentration of fluoride need not indicate cold water. Ratios which have been considered are:  $[F^-]/[OH^-]$  on the grounds that an exchange reaction between these ions controls their concentrations, when the solution is undersaturated with respect to fluorite (Nordström & Jenne 1977, Pálmason et al. 1978); F/Cl whose quantitative application as a geothermometer is prevented by the Ca content (as controlled by the pH and  $CO_3^{--}$  contents) (White 1970). It has been suggested (Pálmason et al. 1978) that at temperatures below  $100^\circ C$  one mineral controls the  $[F^-]/[OH^-]$  ratio in such a way that there is an increase with increasing source temperature but at temperatures above  $100^\circ C$  another mineral is in control and this ratio is relatively constant. In Fig.13 this ratio is drawn against the estimated source temperature (see Chapter 6.3), and it appears that a relationship exists between the two. In fact this relationship is in agreement with the idea, described above, that this ratio increases up to a certain temperature, but becomes constant above this value. The threshold value, however, appears to lie closer to  $80^\circ C$  in this case than the predicted  $100^\circ C$ .

Although the F/Cl ratio cannot be applied quantitatively as a geothermometer it has often proved to be a useful qualitative guide (Mahon 1970). Fig.14 suggests a slightly different pattern than indicated by the geothermometers compared in Table 7.

## 6.8 Isotopic composition.

The results of deuterium ( $\delta D$ ) and oxygen-18 ( $\delta^{18}O$ ) analyses for 6 of the samples are reported in Table 6, and these results are plotted in Fig.15 along with the meteoric line for  $\delta D - \delta^{18}O$  (Craig 1961), a line obtained for East-African lakes (Craig 1961), and a line drawn through three average results for rain at continental African stations (Dansgaard 1964). The rainwater station which lies closest to Burundi is Entebbe. The present results are of the same magnitude, and, as expected, similar to those for continental African rain. There may, however, be a slight oxygen shift, which could result from water-rock

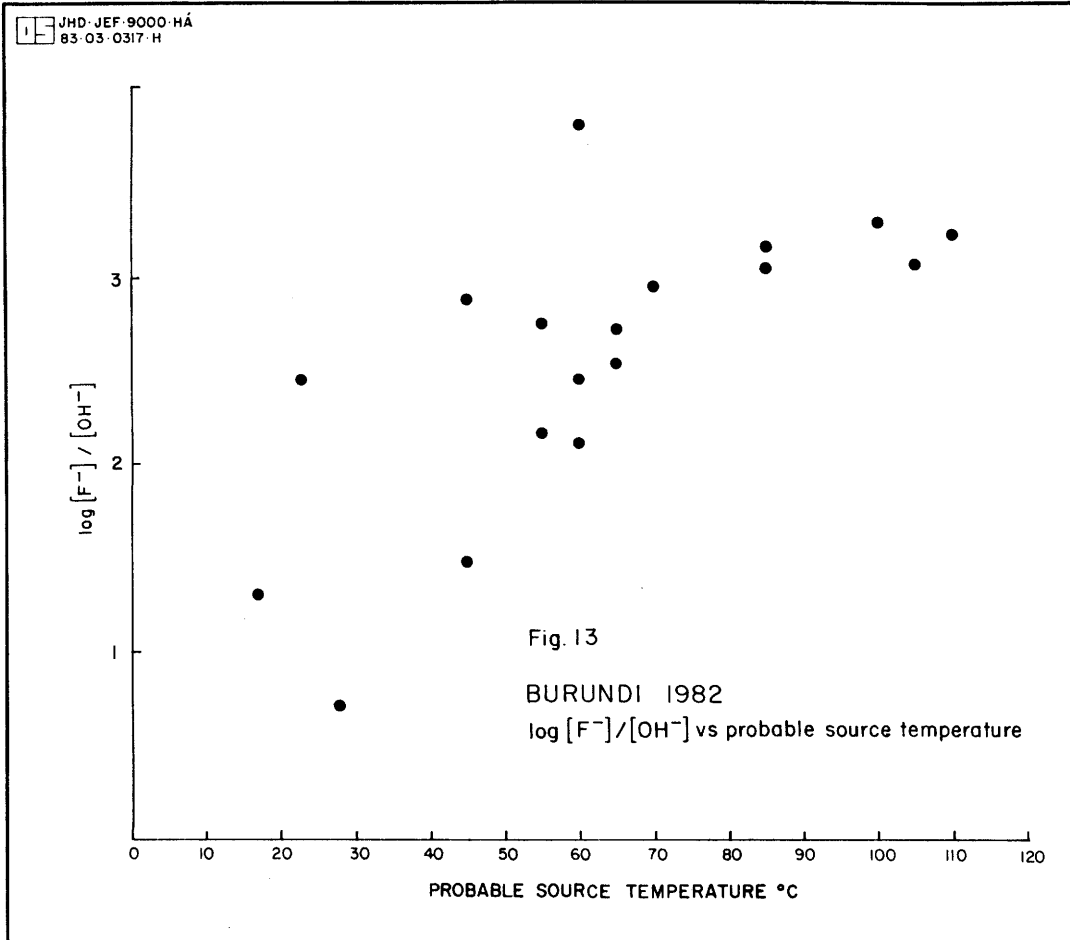

Fig.14. Burundi 1982 F/Cl ( $\times 10^2$ ) distribution

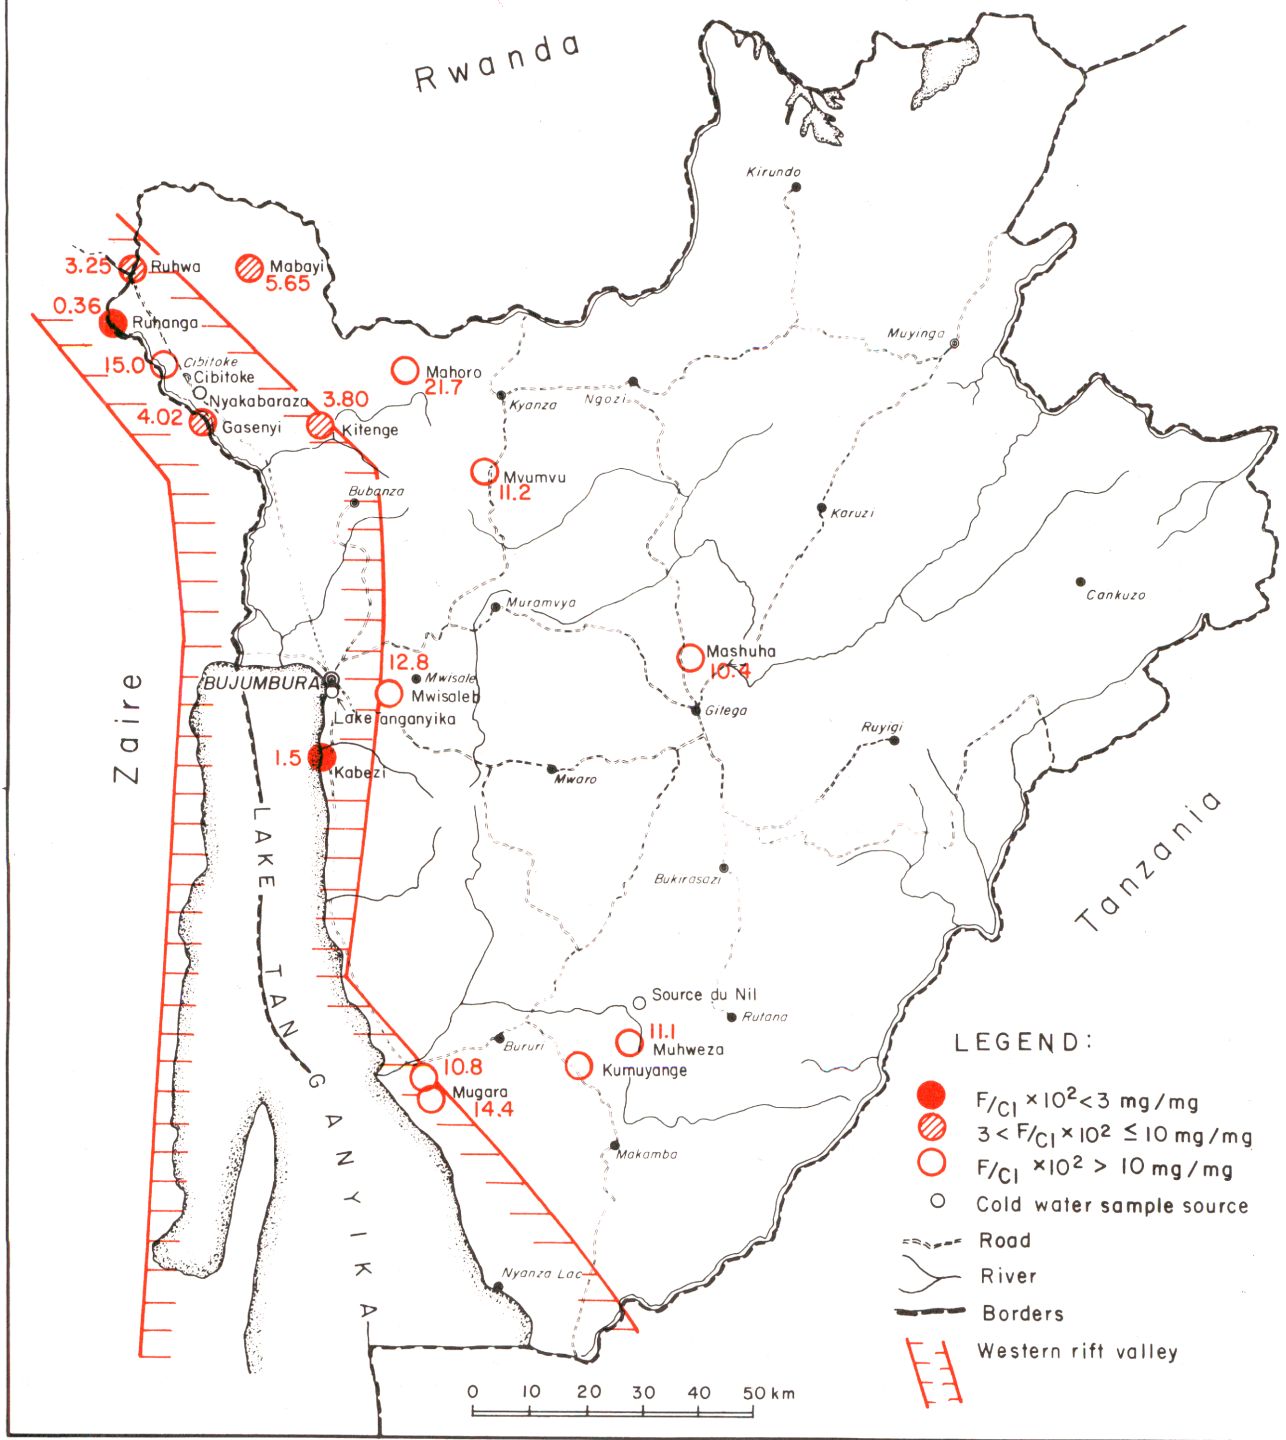

Fig. 15

JHD-JEF-9000.HÁ.  
83.02. 0190. Sy.J.

interaction after the rainfall. There is little variation between the Burundi samples, although the Nyakabaraza sample is a little richer in the heavier isotopes than the rest. As there is a variation in isotopes in rainwater with altitude a difference of this magnitude might result from different origins, i.e. that the water which is more enriched in the heavier isotopes might have fallen as rain in the rift valley at an altitude of 5-700 m.y.s., whereas the rest might have fallen as rain in the mountains at 1500-2000 m.y.s. This explanation invokes a model where the water sampled at Ruhwa and Gasenyi would be assumed to have fallen as rain in the mountains, seeped deep down into the ground, come into contact with a heat source, and emerged again as geothermal water down in the valley after some underground residence time. The Nyakabaraza water on the other hand would be considered to have fallen as rain in the valley. Another possible explanation is that, as before, the high level samples (Source du Nil, Mwisale, Kumuyange) are lighter due to the altitude, and the low level waters all have their origin from rain in the lowland, but that the water from Ruhwa and Gasenyi has had longer residence time underground than the Nyakabaraza water, since there tends to be an annual variation in the isotopic content of the precipitation. The Nyakabaraza water would thus reflect the relatively dry season rain composition which is more enriched in heavy isotopes, due to evaporation effects (Dansgaard 1964), but the Ruhwa and Gasenyi waters would reflect the mean annual composition. Thus the high level samples would also be reflecting the dry season composition. This explanation seems more unlikely, since there is very little rain during the dry season and it is unlikely that it could feed these springs, the apparent oxygen shift in the Nyakabaraza water and its considerable mineralization would be unlikely if it originated in very recent precipitation, and the similarity between the Ruhwa and Gasenyi samples on the one hand, and the high altitude samples on the other would have to be fortuitous. It is tentatively suggested that the Ruhwa and Gasenyi waters originate in the mountains and emerge after considerable underground circulation. The Mwisale and Kumuyange waters probably have much shorter underground residence times, but come into contact with localised relatively powerful heat sources.

Only much more extensive sampling of rainwater and hot and

cold groundwater springs can confirm or refute this conclusion.

## 6.9 Cold groundwater

Results of cold water analyses were obtained from REGIDESO (App. 3). As it was its suitability as drinking water that was being tested, the constituents determined were to a large extent different from those in the present study. However the ones that were comparable are reported in Table 10 along with the results for the cold groundwater samples and the geothermal samples from the present study that were the closest geographically to the REGIDESO samples.

As expected the geothermal waters are generally quite different from their neighbouring cold groundwaters. The differences are, however, not in all cases the ones expected, f.inst. at Mwisale, the cold water is more mineralized than the hot water. Considering the conductivity values, the cold water from Ngozi is apparently more mineralized than both the Mvumvu and Mahoro waters, even though the CO<sub>2</sub> concentrations and the hardness values are higher for the latter ones. In fact, some of the REGIDEO hardness values seem very low, and there may be a question of comparability of values, regarding this parameter. Again going by the conductivity the Kigwena water is more mineralized than the two Mugara waters, although the results for individual constituents are not entirely dissimilar. The Kajondi water is more mineralized than the Muhweza and Kumuyange waters, but the latter have compositions similar to the Source du Nil water. These results support the idea that the hot water sources in the old formations in the mountains such as Mwisale, Mahoro, Mugara, Kumuyange and Muhweza may result from powerful localised heat sources, with which relatively recent rainwater comes into contact, and the residence time of such waters is therefore short. Some of the cold groundwaters apparently have a relatively long underground circulation time.

1) Mean of 4 sources

2) Mean of 2 sources

The situation is quite different in the rift valley where a hot water source such as Ruhanga is much more mineralized than the near-by cold water sources of Nyakabaraza and Rugombo. This suggests a relatively long underground circulation time for the Ruhanga water. The water from Cibitoke is, however, mineralized to a similar extent as these neighbouring cold waters, but this was not considered to be a very hot source. The Ruhwa and Gasenyi waters are similar to the Ruhanga water and the same argument should apply to them, although they lie further away from the cold water sources sampled.

The waters sources of cold springs vary considerably in chemistry. Generally they are neutral or slightly basic. All, except the Source du Nil water, are relatively mineralized.

## 7 RELATIONS BETWEEN GEOTHERMAL MANIFESTATIONS IN THE RUSIZI VALLEY AND THE TSIBINDE VOLCANIC ZONE

The geological and geochemical evidence presented in Chapter 6 indicates that the most promising area for finding potential geothermal systems is in the rift valley in the north-western part of Burundi.

Geological evidence suggests that the area, which includes the Ruhwa, Ruhanga, Gasenyi and Cibitoke springs, is a part of the Tshibinde volcanic zone south of Lake Kivu (Fig.4), indicating that an anomalously high geothermal gradient could be expected in this region. This has in fact been confirmed for Lake Kivu by Degens et al. (1973). Furthermore several geothermal manifestations have been reported in the area by some authors (Degens et al. 1973, Deelstra et al. 1972). Some of these are shown in Fig. 1. Chemical analysis of samples from five localities in Rwanda and N-E Zaire were reported. Some of the results are presented in Table 11 and much similarity is suggested between all samples from the Rusizi valley, from Lake Tanganyika in the south to Lake Kivu in the north. Cap Banza by Lake Tanganyika is a hotter source but totally different in character. The source at Kinanira has not been investigated but information on it could be valuable in view of its closeness to the Ruhanga source. This evidence strongly suggests that geothermal areas within the Tshibinde zone should be regarded as a connected geothermal prospect. Even though they are divided between three countries the best way to investigate the possibilities of discovering economically exploitable sources would be to include the whole of the Tshibinde region in all surveys.

## 8 RECOMMENDATIONS FOR FURTHER RESEARCH

### 8.1 Reconnaissance

There should be no need for further detailed reconnaissance missions covering the whole of Burundi similar to the one described in this report. However, any previously unknown geothermal locations, especially in the Rusizi valley should be investigated in the manner described here.

To obtain meaningful information about the Rusizi valley geothermal areas a similar reconnaissance mission would have to take place, during which all known geothermal locations in the Rwanda and Zaire parts of it would be visited. Such a mission might be effected under the auspices of the E.G.L. (Organization de la C.E.P.C.L. pour l'Energie des Pays des Grands Lacs).

The following recommendations assume that such a reconnaissance mission will be the next step, and that the investigations listed will cover the whole of the Rusizi valley geothermal areas.

### 8.2 Further studies in selected geothermal areas

The question whether a geothermal field is suitable for utilization can only be answered by drilling and direct testing of the area. But due to the high cost of drilling the exploration of a geothermal system usually includes preliminary geological, geochemical and geophysical surveys to obtain the maximum possible information about the system and to minimize the risk of selecting wrong drilling sites. Furthermore an extensive surface reconnaissance can show whether a geothermal field is not promising enough for drilling to be recommended.

If the first phase of the reconnaissance leads to the discovery of a suitable target area for further geothermal

studies, it is recommended that the second phase of the exploration be carried out. This involves geological and geophysical methods.

### 8.3 Geological mapping

A detailed geological map of the prospective area is essential for the study. It should cover the whole of the geothermal field and extend into the surrounding area. Geological formations, folds and faults should be mapped with special emphasis on the younger ones. Furthermore all surface geothermal manifestations should be shown so that possible connections between the structures of the area and geothermal activity can be studied. The aim of the geological mapping is increased understanding of the geothermal system, especially the pointing out of possible heat sources, reservoir rock, cap rock, possible upflow zones and aquifers.

The geologist who carries out the geological work needs to be experienced in geothermal work. One part of the study can be done in the laboratory with the aid of aerial photographs, but a field survey during which the geologist works out a detailed geological map is also necessary. Geoscientific studies in a selected area require maps in the scale 1:50.000 with altitude contours, and also aerial photographs.

### 8.4 Hydrological survey

The energy from a geothermal system is transferred to the surface by means of water or steam. The knowledge about the hydrological character of a geothermal field is therefore very important for the exploitation of the system. If a potential geothermal field will be discovered it is therefore recommended that a hydrological survey be carried out. This involves the mapping of the field's catchment, rainfall pattern, evapotranspiration and run-off water. Thus values for the available water for

ground water recharge would be obtained. During the first stage of the study all available hydrological data will be gathered and evaluated followed by reconnaissance mapping of the groundwater regime in the geothermal prospect area.

The result of such a study is very useful in evaluating the potential of a geothermal system, especially where the amount of available circulation water is sparse as can be expected in Burundi.

### 8.5 Geophysical surveys

Many geophysical methods have been used with success in geothermal research, such as measurements of resistivity, magnetism, gravity, geothermal gradient and seismic activity. The most widely used method in the first stage of a geophysical study is resistivity measurements with a Schlumberger dipole-dipole configuration of electrodes. This method has proved very useful in locating low resistivity bodies, like hot reservoirs and permeable zones, in the uppermost 1200-1400 m of the lithosphere. The detection of geological structures such as faults and other boundaries is another possible result. The application of the method requires a skilled geophysicist, a technician and a group of 3 to 4 assistants. It is time consuming.

### 8.6 Geothermal gradient surveys

The regional geothermal gradient in Burundi is unknown, and if geothermal research is to be continued in the country, an attempt should be made to obtain it by measurements. The first stage would be the measurement of downhole temperatures in some of the already existing narrow research boreholes which have been drilled in Burundi in connection with mineral prospecting (L. Muhagaze, personal communication). Thus the necessary information on the background regional geothermal gradient would be obtained. The drilling of slim 100 m deep drillholes would

be necessary to establish the geothermal gradients in selected geothermal areas of the rift valley.

## 9 CONCLUSIONS

The geothermal manifestations in Burundi are found mainly in two types of environment, i.e. Precambrian rock, mostly outside the rift valley, and sediments inside the valley. The old age and low porosity of the Precambrian rock make the existence of an exploitable geothermal system within it highly unlikely. The higher porosity of the thick sediment layers, and the recent volcanism in the rift valley constitute conditions which could lead to exploitable geothermal systems. There is considerable volcanism around Lake Kivu in whose vicinity geothermal heat has been reported. The chemical composition of the lake water is affected by geothermal heat. The northwestern part of Burundi is on the edge of the Tshibinde volcanic region of Lake Kivu. Thus from a geological point of view this is the most promising of the geothermal areas in Burundi which were investigated during the present mission.

Six geothermal locations in the rift valley were visited, four in the Rusizi valley, one on the east coast of Lake Tanganyika (Kabezi), and one further south at some distance from the lake (the Mugara springs). In the Rusizi valley and at Kabezi the hot water rises from sediments, but at Mugara from Precambrian rock. Thus the former sources are likely to originate from larger and more open aquifers than the latter.

Chemical geothermometers suggest highest source temperatures in the rift valley and the three highest temperatures were estimated at locations in the Rusizi valley. All discharges rising from sediments were carbon dioxide rich. This could indicate the presence of a powerful heat source. The high carbon dioxide concentrations lead to supersaturation with respect to calcium carbonate in some cases, so that care would have to be exercised in avoiding calcium carbonate deposition in the event of exploitation.

In summary an exploitable geothermal source whose temperature could be in the 100 - 160°C range, may exist in the Rusizi valley and probably extend well into Zaire and Rwanda. This source is thought to be connected to the Tshibinde volcanic area south of Lake Kivu. Therefore an anomalously high geothermal gradient may be expected in

this region.

The base temperature in Burundi is unlikely to be high enough for electricity production, but is suitable for many industrial and domestic uses. Of the existing industries in Burundi, the tea factories, the brewery and the textile factory could benefit from such use, and any new industries especially those in which heating and drying are involved could use such an energy source.

The geothermal water in the Rusizi valley is carbon dioxide rich, and a minor exploitation might involve its cooling and bottling as mineral water. The most chloride rich sources would, however, be unsuitable in this respect.

The water rising from Precambrian rock is unlikely to be exploitable for other than direct uses, such as bathing.

It is recommended that further geological, geochemical and geophysical studies be carried out in the whole of the Tshibinde region, subject, of course to an agreement between the three governments involved.

**APPENDIX 1.**

Request letters for development aid in the geothermal field from the Government of Burundi, received by the Icelandic Industry and Foreign Ministries.

Ministère des Travaux Publics,  
de l'Energie et des Mines  
Cabinet du Ministre

HJORLEIFUR CUTTORMOSSON  
Minister of Energy and Industry  
Arnarhvoll . Reykjavik . ICELAND

740/516 /CAB/81

Your Excellency,

Let me tell you how happy I was to make your acquaintance at the Nairobi Conference on new and renewable sources of energy. I was very well impressed by your warm understanding and goodwill towards me and my country, Burundi.

We agreed on your sending us a mission of specialists from Iceland to assist us in the development of geothermal energy.

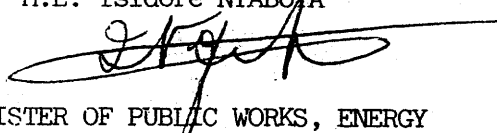

The planning of the sites for different uses: energy, medical cures, mineral water, thermal bathing for tourism might be additional interests to look into.

We are attaching a copy of a first glance report on 14 thermal sources. Really meaningful further investigations of these sites might bring some good results.

We are relying upon your Government's assistance to assess the possibilities. Your interest in the development of Burundi is certainly greatly appreciated.

Yours sincerely.

H.E. Isidore NYABOYA

MINISTER OF PUBLIC WORKS, ENERGY  
AND MINES

BB/PP

AMBASSADE DE LA  
RÉPUBLIQUE DU BURUNDI

REPRÉSENTATION PERMANENTE  
AUPRÈS DE LA COMMUNAUTÉ ÉCONOMIQUE  
EUROPÉENNE

BRUXELLES, LE

N° 516.04/1181/A.E/81

L'Ambassade de la République du Burundi à Bruxelles présente ses compliments à l'Ambassade d'Islande à Bruxelles et a l'honneur de lui demander de bien vouloir transmettre au Gouvernement d'Islande la requête que le Gouvernement du Burundi lui adresse et qui consiste en l'envoi d'un expert en énergie géothermique pour une courte durée.

Cette mission aurait notamment pour but de :

- vérifier et éventuellement compléter les données existantes en ce qui concerne les eaux thermales;
- examiner, à la lumière de la qualité physico-chimique de l'eau, l'usage le plus judicieux pour chaque source;
- proposer un programme d'investigation future pour les études de l'énergie géothermique.

L'Ambassade de la République du Burundi à Bruxelles remercie d'ores et déjà l'Ambassade d'Islande de sa diligence et saisit la présente occasion pour lui renouveler les assurances de sa haute considération.

Fait à Bruxelles, le 26 octobre 1981

APPENDIX 2.
